Sepsis-associated encephalopathy (SAE) has been reported to occur in 8%–80% of patients with sepsis.[29] The criteria to diagnose SAE include the presence of impaired cognitive function, evidence of an extracranial infection and absence of other obvious aetiologies for the altered conscious state. No single pathological mechanism has been identified as the pathogenesis of encephalopathy is thought to be multi-factorial. Alteration in cerebral blood flow induced by mediators of inflammation, generation of free radicals by activated leucocytes, erythrocyte sludging in the microcirculation, breakdown of the blood–brain barrier, cerebral oedema, endotoxin and cytokine-induced reductions in cerebral oxygen utilisation, neuronal degeneration and apoptosis, elevated concentrations of aromatic amino acids resulting in altered neurotransmitter function and increased GABA-mediated neurotransmission, have all been implicated as contributing factors to this pathology.[30,31] Asterixis, tremor and myoclonus – features of other metabolic encephalopathies – are uncommon in SAE. The presence of lateralising signs is extremely rare in SAE and warrants the exclusion of other causes, such as stroke. The mortality of patients with SAE is higher than in those with sepsis without encephalopathy[32] and therapy is largely directed at the underlying septic process.

ICU encephalopathy or ICU syndrome is a term used to describe behavioural disorders that develop in patients 5–7 days after admission to the ICU. Clinically, this may present as agitation, restlessness and frank delirium.[33] The causes are multi-factorial and include, prolonged ventilation, sleep deprivation, distortion of perception with loss of day–night cycles, immobilisation, an over-stimulating environment and monotony. These factors coupled with the administration of multiple sedatives and neurological consequences of the underlying disease can precipitate behavioural disturbance in the ICU. It is important to bear in mind that this is a diagnosis of exclusion and that all other reversible causes must be excluded before this diagnostic label is applied. There is a significant overlap between this syndrome and that of delirium and ICU encephalopathy may be best conceptualised as a form of ICU-specific delirium that arises in the overly stimulating environment of a busy ICU.[34] The Confusion Assessment Method for ICU (CAM-ICU) is an assessment tool for the identification ICU-specific delirium. [35] It utilises a series of simple questions and tasks to assess the presence of four key features of delirium, fluctuating mental status, inattention, altered level of consciousness and disordered thinking. Importantly, these tasks can be performed by patients who are unable to verbalise answers due to endotracheal intubation. Management of ICU delirium is a complex area that requires further research, we refer the interested reader to Chapter 65 on delirium within this volume.

Prognosis in Disorders of Consciousness

Drug-induced disorders of consciousness usually have a good prognosis unless hypoxia and hypotension have resulted in severe secondary insults. Coma following head injury has a statistically better outcome compared to non-traumatic coma (coma occurring during the course of a medical illness). In non-traumatic coma lasting for 6 hours or more, only 15% of patients make a meaningful recovery to be able to return to their pre-morbid state of health. [37] The prognosis following anoxic coma has been described in a separate section. Within the non-traumatic coma category, coma resulting from infection, metabolic causes and multiple organ dysfunction syndrome have a better outcome compared to anoxic coma. [37] The level of consciousness on admission is also relevant to prognosis, with patients manifesting a GCS score of 3–6, recording a significantly higher in-hospital mortality rate, as compared with those with a GCS of 7–10 (32.9% vs. 17.9%), in one prospective study of non-traumatic coma. [38]

A number of outcome scales have been developed to assess neurological recovery following brain injury. [39] These include the Barthel index, the Modified Rankin scale and the Glasgow outcome scale (GOS). The GOS is widely used to assess recovery after traumatic brain injury. It has five broad categories: 1 = good recovery, 2 = moderate disability, 3 = severe disability, 4 = persistent vegetative state and 5 = death. It is simple, easy to administer and has been reported to have good inter-rater agreement. The Glasgow Outcome Scale – Extended (GOSE) expands on the GOS with an 8-point scale that further breaks down good recovery, moderate disability and severe disability into lower and upper categories, and is utilised more frequently in clinical trials and research studies. [40] Other outcome measures commonly used to follow patient recovery include the WHODAS and EQ-5D-5L, which are focused on functional status.

Treatment Options in Coma

No effective standardised treatment exists for patients in states of coma. [41] Currently, evaluated interventions can be divided into pharmacological and non-pharmacological measures. Pharmacological measures include the use of progesterone, levodopa and amantadine. Initial trials reported some recovery response in terms of reduction in spasticity and improved cognitive behaviour and communication, such as following simple commands. Giacino et al. found a significant improvement in the Disability Rating Scale following administration of amantadine in patients with traumatic brain injury who were in a vegetative or minimally conscious state. [42] However, the administration of progesterone was not associated with improved GOS following TBI. [43] Zolpidem has also been trialled in patients with traumatic and anoxic aetiologies of reduced consciousness, and results have been variable. [44] Whilst some investigators report enhanced verbal, motor and cognitive functions, these have not been reproduced in other small trials. Moreover, the duration of the effects of zolpidem is short. Bromocriptine and intrathecal baclofen have also been tried, but no large-scale studies have been reported.

Non-pharmacological measures include deep brain stimulation, extradural cortical stimulation, spinal cord stimulation and median nerve stimulation. [45] Thibaut et al. demonstrated that the application of left dorsolateral prefrontal cortex transcranial direct current stimulation transiently improved signs of consciousness in patients in a minimally conscious state, although the overall outcome did not change. [46] Whilst reports of improved responsiveness have been published, the evidence is largely anecdotal, and data from large studies are lacking.

Conclusion

An altered level of consciousness is common in critical illness. It is associated with a wide range of underlying pathologies. Some of these pathologies are medical emergencies with profound implications for patient outcomes. We advocate an aggressive approach to investigation and treatment in this patient group as a means of identifying pathology early and minimising secondary brain injury. We have sought to provide a basic framework with which to approach this group of clinical scenarios and would encourage the reader to review associated chapters within this text that cover specific conditions in greater detail.

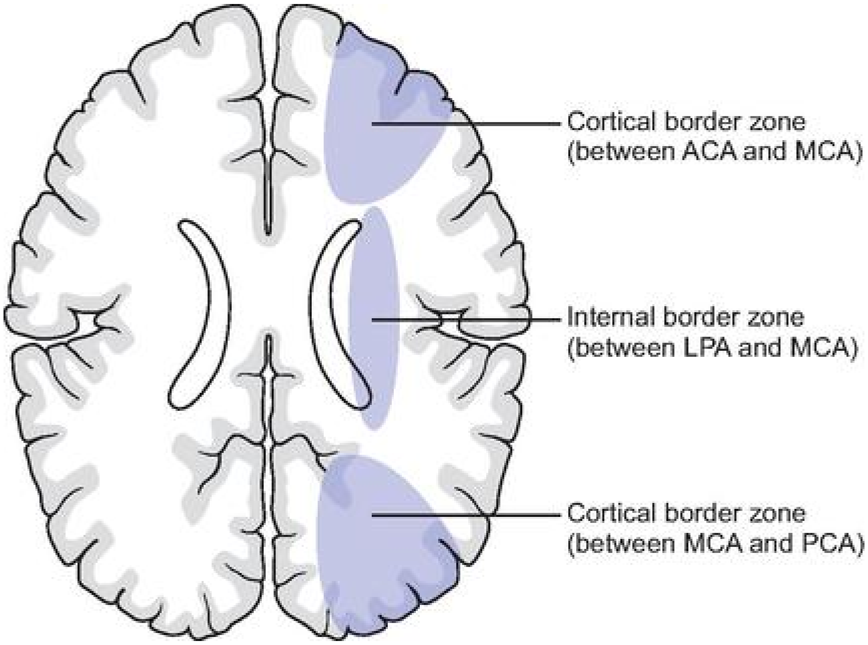
Cerebral protection

Colin Andrew Eynon

Cerebral Physiology and Anatomy

The brain receives around 15% of the cardiac output (50 mL/100 g/min) and utilises around 3–5 mL O_2/min per 100 g tissue and 5 mg glucose/min per 100 g tissue. The grey matter of the brain, which consists primarily of the neuronal cell bodies and synapses, has a higher blood flow compared with the white matter, which consists largely of fibre tracts. Critical cerebral blood flow (CBF) is around 20 mL/100 g/min, with the electroencephalogram (EEG) becoming isoelectric at 15 mL/100 g/min.

The anterior cerebral circulation is supplied by the two internal carotid arteries which subdivide into the anterior and middle cerebral arteries. These provide around 70% of the cerebral circulation, supplying the frontal, parietal and temporal lobes and the anterior diencephalon (basal ganglia and hypothalamus). The two vertebral arteries join to form the basilar artery which supplies the posterior circulation; the brainstem, cerebellum, occipital lobes and the posterior diencephalon (thalamus). The two circulations (anterior and posterior) are joined by communicating arteries to form the circle of Willis at the base of the brain. As the circle facilitates collateral flow, obstruction to one of the four principal arteries (right and left internal carotid, right and left vertebral) supplying the brain may be clinically insignificant. Damage to the intracerebral vessels, however, often results in significant damage due to the lack of anatomical reserve. The areas between those supplied by the principal cerebral arteries are supplied by the leptomeningeal arteries. These areas are potential watershed areas that are particularly at risk in conditions of low- or no-flow such as cardiac arrest, severe sepsis or following major trauma (Fig. 60.1).



Cortical border zone
(between ACA and MCA)
Internal border zone
(between LPA and MCA)
Cortical border zone
(between MCA and PCA)

The diagram displays an axial view with the following arterial territories marked on the right: Cortical border zone between ACA and MCA, internal border zone between LPA and MCA, cortical border zone between MCA and PCA.

FIG. 60.1 Axial view of the brain showing the major arterial territories. Watershed infarcts may occur at the border between the major cerebral arterial territories in conditions of low blood flow. These may be (A) cortical border zone infarcts (infarction of the cortex and neighbouring subcortical white matter at the border of the ACA and the MCA and/or the MCA and the PCA), or (B) internal border zone infarction of deep white matter (between the LPA and the deep cortical branches of the MCA or at the border zone of deep white matter branches of the MCA and the ACA). *ACA,* Anterior cerebral artery; *LPA,* lenticulostriate perforating arteries; *MCA,* middle cerebral artery; *PCA,* posterior cerebral artery.

Cerebral Perfusion

Cerebral perfusion is controlled in part by the perfusion pressure across the brain (cerebral perfusion pressure or CPP). CPP is the difference between cerebral arterial pressure and cerebral venous pressure. As these pressures are difficult to measure, systemic mean arterial pressure (MAP) and intracranial pressure (ICP) are used as surrogates.

$$\mathrm{CPP} = \mathrm{MAP} - \mathrm{ICP}$$

MAP can be estimated as equal to diastolic blood pressure + 1/3 pulse pressure.

When calculating CPP, the arterial transducer used to estimate MAP should be positioned at the level of the tragus. In adults, the normal resting ICP is 0–10 mm Hg. ICP can rise to 50 mm Hg or higher during straining or sneezing with no impairment in cerebral function. It is not therefore an elevated ICP alone that is important in pathological conditions. CPP is around 60 mm Hg in the normal state.

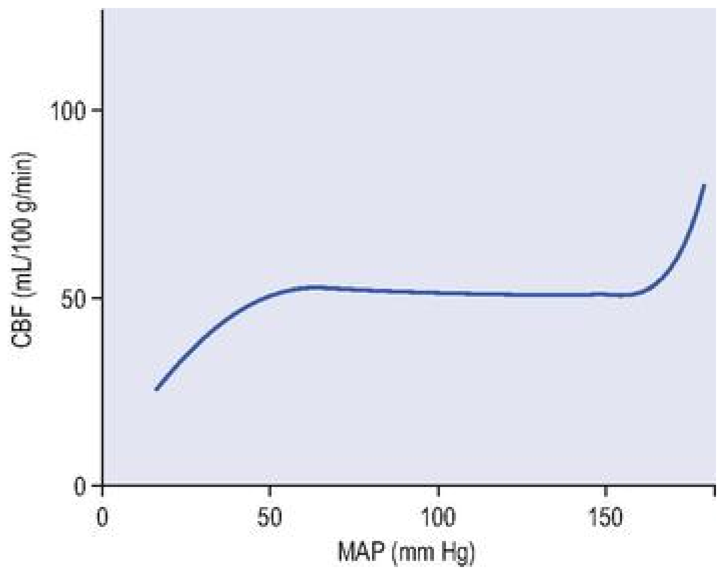
Cerebral Metabolism

The energy requirements of the brain are large to maintain membrane integrity and to support the transmembrane ion gradients required for electrical activity and cell survival. Energy is also required for the synthesis, storage and release of neurotransmitters. Neurons produce adenosine triphosphate almost entirely by the oxidative metabolism of glucose and ketone bodies. Over 85% of the glucose used by the brain undergoes oxidative metabolism with brain tissue having only very limited ability for anaerobic metabolism. Consciousness is lost rapidly if the supply of either oxygen or glucose is restricted. Loss of consciousness will occur in less than 10 seconds following acute decompression at 50,000 ft, with the time delay resulting from the transit time of deoxygenated blood from the lungs to the brain.[1] Similarly, unconsciousness occurs swiftly following intravenous administration of high doses of insulin.[2]

Local Control of Cerebral Blood Flow

Autoregulation (Myogenic Regulation)

Autoregulation ensures that CBF remains constant between MAPs from 60 to 160 mm Hg. The stimulus for autoregulation is CPP. Autoregulation is thought to be a myogenic mechanism with reflex vasoconstriction of cerebral vessels occurring in response to increases in CPP and vascular wall tension and vasodilatation occurring in response to decreases in CPP and reduction in wall tension.[3] Outside the values where autoregulation is effective, the relationship between CBF and MAP is linear and CBF is pressure dependent (Fig. 60.2). The range at which autoregulation can operate varies with age and in certain pathological conditions. The range is shifted to the left in early life and to the right in chronic hypertension. A rapid reduction in the blood pressure of a patient with chronic hypertension risks inadequate perfusion of the brain, heart and/or kidneys. Autoregulation may also be impaired by hypoxia, ischaemia, hypercapnia, trauma and certain anaesthetic agents.



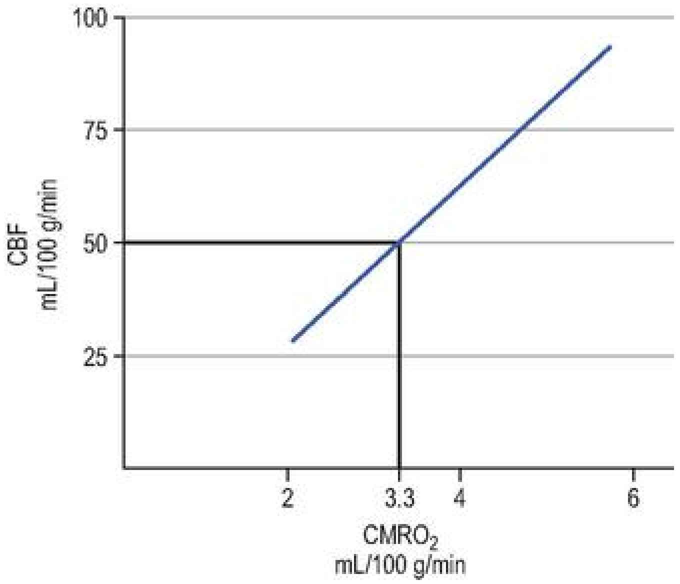
The line graph presents cerebral blood flow in millilitres per 100 grams per minute on the vertical axis and mean arterial pressure in millimetres of mercury on the horizontal axis. The curve begins with an upward slope, then becomes nearly horizontal, forming a plateau between approximately 50 to 150 millimetres of mercury, and finally rises sharply beyond 150 millimetres of mercury.

FIG. 60.2 The relationship between mean arterial pressure *(MAP)* and cerebral blood flow *(CBF)* under normal circumstances, illustrating the range of autoregulation.

Rapid rises in systemic blood pressure are also poorly tolerated. Hypertensive emergencies occur in an estimated 1–2/100,000 patients per year and may be associated with retinopathy, papilloedema or encephalopathy. Hypertensive encephalopathy results from cerebral oedema due to increased hydrostatic pressures and can cause drowsiness, coma, seizures and ICH. Posterior reversible encephalopathy syndrome (PRES) may present with seizures, disturbed vision, headache and altered mental state. [4] PRES is strongly linked to conditions that co-exist in patients with renal disease, such as hypertension, vascular and autoimmune diseases, immunosuppression and organ transplantation. More than 70% of patients are hypertensive. Typical magnetic resonance imaging (MRI) findings in PRES are of reversible, symmetrical, posterior subcortical vasogenic oedema. [5] If promptly treated and managed, symptoms often resolve within a few days to weeks.

Flow–Metabolism Coupling

Flow–metabolism coupling is the direct relationship of the metabolic activity of the brain to CBF. Increases in metabolic demand are met rapidly by increases in CBF and delivery of substrates (Fig. 60.3). The exact mechanisms that control flow–metabolism coupling are unknown but may involve a variety of mediators. It is not clear how the diameter of cerebral vessels upstream to the area of activity can be altered so rapidly by metabolic products which are being washed downstream. It is thought that there may be control neurons that act on specific cerebral vessels that control local blood flow. [6] Regional variations in cerebral metabolism can now be visualised using techniques such as positron emission tomography scanning, although the hypothesis that such variations existed dates as far back as 1890. [7]



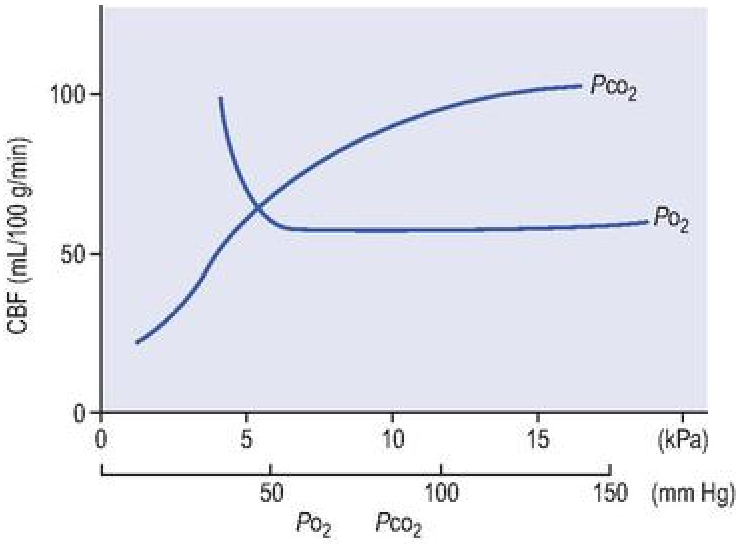
The line graph illustrates cerebral blood flow in millilitres per 100 grams per minute on the vertical axis and cerebral metabolic rate of oxygen in millilitres per 100 grams per minute on the horizontal axis. A horizontal line extends at a cerebral blood flow value of 50 until the cerebral metabolic rate of oxygen reaches three point three. A slanting line rises at around a cerebral blood flow value of 25 and intersects at a cerebral metabolic rate of oxygen value of three point three and continues upward with a positive slope.

FIG. 60.3 Flow–metabolism coupling. As the cerebral metabolic rate for oxygen *($CMRO_2$)* increases there is proportional increase in cerebral blood flow *(CBF)* . Normal CBF is around 50 mL/100 g/min.

Systemic Control of Cerebral Blood Flow

Carbon Dioxide

CBF increases by 3%–4% for each mm Hg increase in $PaCO_2$. A doubling of $PaCO_2$ doubles CBF and conversely, a halving of $PaCO_2$ will halve CBF (Fig. 60.4). The responses to changes in $PaCO_2$ occur rapidly, within 30s, and are thought to relate to changes in extracellular or interstitial hydrogen ion concentrations. Tight control of $PaCO_2$ is essential if CPP is critical; increases in CO_2 cause vasodilatation and increased ICP, whereas decrease in $PaCO_2$ below 30 mm Hg (4 kPa) have been shown to result in vasoconstriction sufficient to precipitate critical cerebral ischaemia. [8] Impaired CO_2 reactivity is associated with poor outcomes in patients with severe head injury. [9]



The line graph depicts cerebral blood flow in millilitres per 100 grams per minute on the vertical axis and partial pressures of oxygen and carbon dioxide on the horizontal axis. The horizontal axis is labelled with partial pressure of oxygen and partial pressure of carbon dioxide in millimetres of mercury and kilopascals. The curve for the partial pressure of carbon dioxide rises steadily, which shows a direct relationship with cerebral blood flow. The curve for partial pressure of oxygen decreases initially and then plateaus, which shows an inverse and then minimal effect on cerebral blood flow.

FIG. 60.4 The relationship between the partial pressure of oxygen and carbon dioxide and cerebral blood flow *(CBF)* .

Oxygen

CBF is not affected by changes in PaO_2 within the normal range, but levels <50 mm Hg (6.65 kPa) result in cerebral vasodilatation and increases in

CBF. Below 30 mm Hg (4 kPa), CBF is roughly doubled compared with a normal PaO2, with a consequent increase in ICP (see Fig. 60.4).

Temperature

The cerebral metabolic rate for oxygen ($CMRO_2$) is reduced by around 8% for each degree Celsius reduction in temperature. The application of cooling to unselected patients with TBI is now thought to be ineffective in improving neurological and mortality outcomes.[10] Avoidance of hyperthermia in cerebral injury remains important as $CMRO_2$ is increased by a similar amount for every degree Celsius increase in temperature. The European Resuscitation Council and European Society of Intensive Care Medicine recommend the prevention of fever for at least 72 hours for patients who remain in a coma following resuscitation from cardiac arrest.[11]

Cerebral Injury

Cerebral injury is commonly divided into primary and secondary. Primary injuries include traumatic, ischaemic or hypoxic and may be focal or global. Primary traumatic injury may result in four main pathological conditions which can all co-exist: brain contusions, axial and extra-axial haematomas (subdural, extradural and intracerebral), traumatic subarachnoid haemorrhage (SAH) and diffuse axonal injury (DAI). DAI results from dynamic deformation of the brain with resultant shearing forces, affecting the blood vessels and axons. Areas commonly affected include axons in the brainstem, the parasagittal white matter near the cerebral cortex and the corpus callosum.[12]

Focal hypoxic or ischaemic insults often occur acutely, such as in acute stroke. If the area supplied by the affected artery has a good collateral supply, brain injury may be modest. If the area is poorly supplied, cell death will occur within minutes without reperfusion. Around areas of infarction, there is an ischaemic penumbra. Interventions to preserve cerebral function in the penumbral area are key to optimising outcomes.

Global hypoxic-ischaemic conditions are often secondary to respiratory or cardiovascular insufficiency, seen most severely in cardiorespiratory arrest. Recovery depends on the rapid reversal of the primary cause. MRI examinations of patients with persistent disorders of consciousness following resuscitation from cardiac arrest have shown regions of pathological white matter signals in the frontal and occipital lobes and in the periventricular regions. [13] The total volumes of the lesions have been associated with the severity of the patient's outcomes. These patterns demonstrate the different vulnerabilities of particular areas of the brain to ischaemia-hypoxia.

Secondary brain injury may be initiated as a consequence of the primary injury. The duration and severity of secondary insults can have a significant effect on patient outcomes (Table 60.1) and present an opportunity for prevention or early clinical intervention. [14–17] Intracranial secondary injury may be caused by the expansion of intracranial haematomas or the development of cerebral oedema causing pressure effects on more distant parts of the brain, distortion of blood supply or further axonal shearing. Shift of vital structures can ultimately lead to herniation of the brain. Secondary seizure activity can rapidly deplete the brain's supply of metabolites. Systemic secondary insults include hypoxia, hypotension, hyper- or hypocarbia, hyperthermia, hyper- and hypoglycaemia, anaemia and electrolyte disturbances.

Table 60.1

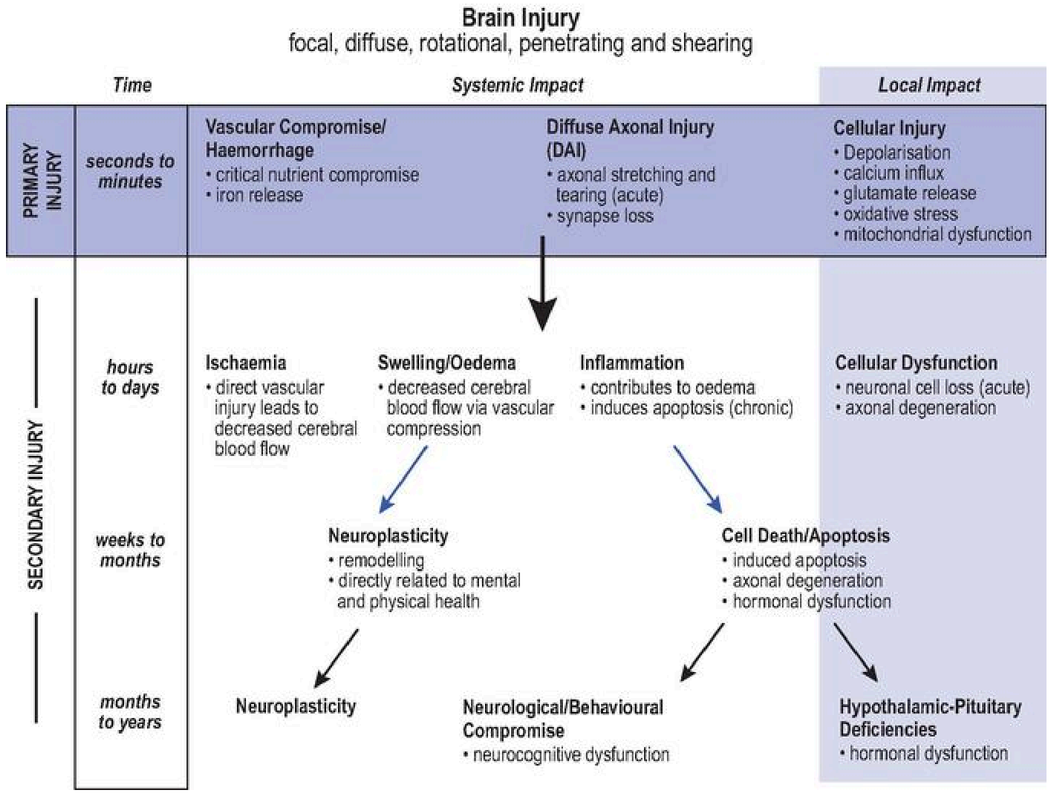
CPP, Cerebral perfusion pressure; *ICP,* intracranial pressure; Sa_{O_2} , peripheral oxygen saturation; *SBP,* systolic blood pressure.

Anaemia has been associated with poorer outcomes in traumatic brain injury (TBI), aneurysmal SAH, ICH and ischaemic stroke. Transfusion improves brain oxygenation in some patients with TBI. [18] Most critical care units now adopt a restrictive strategy to red cell transfusion using trigger haemoglobin around 7–8 g/dL. In patients with TBI, neither administration of erythropoietin nor maintaining a haemoglobin concentration >10 g/dL has resulted in improvement in neurological outcome and the 10 g/dL threshold was associated with a greater incidence of adverse events. [19]

The brain is particularly vulnerable to disturbances of osmolality. [20], [21] Under physiological conditions, brain osmolality is in equilibrium with extracellular fluid osmolality. When acute hyponatraemia occurs, the reduction in plasma osmolality causes water movement into the brain along the osmotic gradient, causing cerebral oedema. Cerebral volume increases by around 7% for every three milli-osmolar reduction in osmolality.

Metabolic and Biochemical Processes in Cerebral Injury

The pathophysiology of brain injury is complex (Fig. 60.5). Even brief disturbances in CBF and delivery of substrates can initiate a cascade of events leading to cellular death. [22] Different areas of the brain have differing thresholds for damage, with the cell bodies (grey matter) being more resilient than the white matter (axons). Anaerobic metabolism results in intracerebral acidosis with accumulation of lactic acid and hydrogen ions. Loss of the normal homeostatic mechanisms responsible for the maintenance of ion gradients results in abnormal sodium, potassium, calcium and chloride movements and the failure of glutamate reuptake into cells. Glutamate and aspartate are the main excitatory neurotransmitters in the brain. When uptake mechanisms fail, toxic levels of glutamate can accumulate in the extracellular space, causing a surge of neuronal activity and membrane depolarisation. The increases in intracellular calcium and sodium activate pathways mediated by Ca^{2+} -dependent enzymes. The restriction of oxygen and substrates to mitochondria induces a cellular metabolic crisis with disruption of cell membranes and organelles, activation of cellular apoptosis, activation of macrophages and platelet aggregation causing secondary disturbances of the microvasculature. Cytotoxic oedema occurs due to the failure of ionic pumps with subsequent ion and fluid shifts. Vasogenic oedema is due to mediator release with damage to endothelium, basement membranes and glial cells with breakdown of the blood-brain barrier.



Brain Injury
focal, diffuse, rotational, penetrating and shearing
Time
Systemic Impact
Local Impact
PRIMARY INJURY
seconds to minutes
Vascular Compromise/ Haemorrhage
• critical nutrient compromise
• iron release
Diffuse Axonal Injury (DAI)
• axonal stretching and tearing (acute)
• synapse loss
Cellular Injury
• Depolarisation
• calcium influx
• glutamate release
• oxidative stress
• mitochondrial dysfunction
SECONDARY INJURY
hours to days
Ischaemia
• direct vascular injury leads to decreased cerebral blood flow
Swelling/Oedema
• decreased cerebral blood flow via vascular compression
Inflammation
• contributes to oedema
• induces apoptosis (chronic)
Cellular Dysfunction
• neuronal cell loss (acute)
• axonal degeneration
weeks to months
Neuroplasticity
• remodelling
• directly related to mental and physical health
Cell Death/Apoptosis
• induced apoptosis
• axonal degeneration
• hormonal dysfunction
months to years
Neuroplasticity
Neurological/Behavioural Compromise
• neurocognitive dysfunction
Hypothalamic-Pituitary Deficiencies
• hormonal dysfunction

The flowchart outlines the progression of brain injury over time, divided into systemic and local impacts across four time intervals. At the top, primary injury occurs within seconds to minutes and includes vascular compromise or haemorrhage, diffuse axonal injury, and cellular injury. These lead to secondary injuries, such as ischemia, swelling or oedema, and inflammation from hours to days, which causes reduced cerebral blood flow, oedema, and apoptosis. This triggers secondary injury over weeks to months, which results in neuroplasticity, cell death, and neurological or behavioural compromise. In local impact, cellular injury leads to dysfunction, which includes acute neuronal cell loss and axonal degeneration. Over months to years, long-term effects include neuroplasticity, neurocognitive dysfunction, and hypothalamic-pituitary deficiencies.

FIG. 60.5 Hypothesised model for progression from primary to secondary injury after trauma to the central nervous system. (Modified with permission from Reifschneider K, Auble BA, Rose SR. Update of endocrine dysfunction following paediatric traumatic brain injury. *J Clin Med* . 2015;4(8):1536–1560.)

Cerebral Protective Strategies

For all patients, including those with brain injury, the priorities are the assessment and management of airway, breathing and circulation (ABC) over the assessment of the neurological status (D – disability). For patients who have sustained major trauma, control of catastrophic haemorrhage is now included before ABC (C-ABC). Cerebral protective strategies should start pre-hospital to maximise the opportunities for a good neurological outcome.

Airway

Recommendations regarding securing the airway in patients with brain injury include those patients with the following[23] :

- Glasgow Coma Score ≤ 8, or with a significantly deteriorating conscious level (i.e. fall in GCS of ≥ 2 points or fall in motor score of ≥ 1 point)
- Loss of protective laryngeal reflexes
- Hypoxia (PaO_2 <13 kPa/98 mm Hg on oxygen). A lower target can be accepted for acute ischaemic stroke
- Hypercarbia ($PaCO_2$ >6 kPa/45 mm Hg)
- Spontaneous hyperventilation causing $PaCO_2$ <4.0 kPa/30 mmHg
- Bilateral fractured mandible or copious bleeding into the mouth (e.g. from skull base fracture)
- Seizures

The projected clinical course of the patient should also be considered. Those requiring transfer for definitive care or who are likely to require surgery for other conditions may require early intubation.

Oxygen

Appropriate, targeted oxygen therapy is essential in the management of brain injury, and avoidance of hypoxia is pivotal. Despite this, the National Confidential Enquiry into Patient Outcome and Death (NCEPOD) report, ‘Trauma: Who Cares?’ published in 2007 found that administration of oxygen was only documented to have occurred in 78% of patients with neurological injury and that peripheral oxygen saturations of <95% occurred in 28% of patients pre-hospital. [24] In mechanically ventilated patients with TBI, avoidance of hypoxia may require the application of positive end-expiratory pressure (PEEP), especially in patients with polytrauma. Although there is a theoretical risk that the increase in intrathoracic pressure can cause increased cerebral blood volume (CBV) and ICP, the application of moderate to high PEEP has not been associated with increased mortality. [25] National Institute for Health and Clinical Excellence (NICE) recommendations are that patients with acute stroke should have supplemental oxygen if the peripheral oxygen saturations fall below 95%. [26]

Carbon Dioxide

Tight control of $PaCO_2$ is required for all mechanically ventilated patients with acute cerebral injury. This can create difficulties in patients with co-existent lung disease or acute respiratory distress syndrome (ARDS) where a balance needs to be struck between the effects of a raised $PaCO_2$ on the brain and lung-protective strategies. [27–29] As detailed earlier, a target $PaCO_2$ of 4.5–5 kPa (35–40 mm Hg) is usual in the acute stages of injury when ICP control is required.

Cerebral Perfusion (Blood Pressure Targets)

Cerebral perfusion depends on MAP and ICP. If the ICP is elevated due to the presence of intracranial haemorrhage or swelling, MAP must be increased to maintain CPP. Many patients with isolated acute intracranial injury have an initial period of arterial hypertension. This will often reduce spontaneously or with simple measures such as analgesia, relieving hypoxia or hypercarbia and ensuring that the patient does not have other systemic disturbances such as urinary retention. There have been concerns that reducing the blood pressure acutely may risk the perfusion of penumbral areas and worsen the clinical outcome.

In patients with acute ischaemic stroke, the blood pressure needs to be less than 185/110 mm Hg prior to administration of thrombolytic therapy and controlled <180/105 mm Hg for the next 24 hours thereafter.[26] NICE also recommends rapidly lowering the blood pressure for those patients with an acute intracerebral haemorrhage who present within 6 hours of onset, who have a systolic blood pressure of 150–220 mm Hg and who do NOT have an underlying structural cause (e.g. tumour, arteriovenous malformation or aneurysm), or where neurosurgery is being undertaken to evacuate the haematoma. The aim should be to reduce the systolic blood pressure to <140 mm Hg with the drop not exceeding 60 mm Hg in the first hour of treatment.[26]

For patients who are unconscious following TBI, it is generally recommended that the MAP target should be >80 mm Hg with the presumption that ICP is at least 20 mm Hg. This can present a challenge, especially with multiple injured patients.[30] A patient who is hypotensive despite resuscitation should ideally not be transported to specialist care until the cause has been identified and the patient stabilised. Persistent hypotension will significantly adversely affect the neurological outcome.

Fluids

Isotonic crystalloid and blood (if required) are the mainstays of fluid replacement in patients with cerebral injury; 0.9% saline is the only isotonic, crystalloid solution that is commonly available. Gelatins, albumin, Ringer’s lactate (compound sodium lactate), Ringer’s acetate and Plasma-Lyte should be avoided as all are hypotonic when real osmolality (mOsm/kg) is measured. The Brain Trauma Foundation (BTF) recommends that the sodium be kept >140 mmol/L for patients with TBI. [31] This avoids the risk of worsening cerebral oedema. Hyperosmolar therapy such as mannitol (2 mL/kg of a 20% solution) or hypertonic saline (2 ml/kg of 3% saline) are often used when ICP is critically elevated. Despite the clear effectiveness on measured ICP, there remains little evidence of improvement in clinical outcomes. [32]

Positioning 30 Degrees Head Up (With Spinal Precautions)

Important, simple steps that can reduce ICP include measures such as elevating the head of the bed by 30 degrees and ensuring the head is in a neutral position and in alignment with the body. For patients with potential spinal injuries, the whole bed can be tilted.

Temperature Control

Pyrexia is common following acute brain injury. Vigilance for possible infective sources, drug reactions or physical causes such as venous thromboembolism is essential. Central (neurogenic) fever is thought to result from a disturbance of temperature regulation in the hypothalamus. It is uncommon and characterised by a constant fever which is often >40°C. As the normal regulatory point has been altered, patients will characteristically have an absence of the measures normally taken to mitigate hyperthermia, such as sweating. [33] Maintenance of normothermia is common practice in specialist intensive care units (ICUs).

Sedation/Analgesia

Patients requiring intubation for cerebral protection are usually managed using a rapid sequence induction technique (with in-line stabilisation of the cervical spine for those with potential trauma). [23] The use of an opiate is recommended to mitigate rises in ICP. The induction agent and dose used should be chosen to ensure the maintenance of an adequate MAP.

Commonly, barbiturates or propofol are used. Ketamine may be useful in patients who are haemodynamically unstable. The concerns regarding potential increases in ICP and cerebral metabolic rate with ketamine appear to be clinically unfounded.[34,35] Following intubation and ventilation, sedation in brain-injured patients is commonly maintained with continuous intravenous infusions of propofol or midazolam. Both reduce the cerebral metabolic rate for oxygen and CBF. High doses are often required to decrease the ICP. Use of continuous infusions of an opioid may help in reducing the amount of sedative required especially if there are concerns regarding propofol infusion syndrome.

Seizure Control

Risk factors for early seizures following trauma (within 7 days of injury) include: Glasgow Coma Score (GCS) ≤10; immediate seizures, post-traumatic amnesia >30 minutes, linear or depressed skull fracture, penetrating head injury, subdural, epidural, or intracerebral haematoma, cerebral contusions, age ≤65 years, or chronic alcoholism.[31] Post-traumatic epilepsy is defined as recurrent seizures occurring more than 7 days following injury. The BTF recommends the use of phenytoin to decrease the incidence of early seizures only when the overall benefit is felt to outweigh the potential complications associated with treatment.[31] Levetiracetam is increasingly used as a first-line anti-convulsant in TBI as mentioned by the Association of Anaesthetists.[23] The ongoing MaST study (Management of seizures after TBI) aims to define best practice in the use of anti-epileptic drugs for patients following TBI.

Seizures occur at the time of bleeding in around 7% of patients with SAH.[36] Another 10% will develop seizures over the first few weeks. Risk factors for early seizures include middle cerebral artery (MCA) aneurysm, thickness of acute subarachnoid clot, associated ICH, re-bleeds, cerebral infarction, poor neurological grade and mode of treatment (endovascular treatment has a lower risk of seizures).[36] The European Stroke Organisation recommends anti-epileptic treatment only for those patients with overt seizures. The American Heart Association (AHA)/American

Stroke Association guidance states that prophylactic anticonvulsants should not be routinely used but can be considered in high-risk patients. [37]

Seizures occur in <16% of patients within 1 week after ICH. A cortical location of the ICH is the most important risk factor for early seizures. Prophylactic anticonvulsant medication has not been shown to be beneficial and the AHA recommends only treatment of clinical seizures. [38]

Glucose Control

Hyperglycaemia has been associated with poorer outcomes for a wide range of acute neurological conditions including TBI, SAH, ICH and acute ischaemic stroke. [39] Studies of tight glycaemic control have been disappointing and guidelines recommend the avoidance of both hyperglycaemia and hypoglycaemia.

Specific Pharmacological Interventions

Although many potential neuroprotective agents have been tried, most clinical studies have failed to show outcome benefits. [22] Nimodipine is used to prevent cerebral vasospasm following aneurysmal SAH. [40] The lack of evidence regarding pharmacological interventions emphasises the importance of the adoption of simple protective measures and rapid access to specialist care.

Specialist Monitoring

A detailed review of neuromonitoring is provided in Chapter 62 .

Status epilepticus

Lara Prisco, Mario Ganau and Arjune Sen

Definition and Epidemiology

Status epilepticus (SE) is considered the most extreme manifestation of seizures and constitutes a neurological emergency. It involves prolonged seizure activity necessitating immediate intervention to prevent irreversible brain damage. SE has an annual incidence of 10–41 cases per 100,000 population with a peak incidence in children under 1 year of age and a directly proportional increase with older age in adults.[1]

In 2015, the International League Against Epilepsy (ILAE) redefined SE as ongoing seizures persisting for longer than 5 or 10 minutes (time 1 or t_1) depending on the type of SE (tonic-clonic SE or focal SE with impaired consciousness, respectively). This timepoint corresponds to the first operational dimension of SE t_1 which defines when treatment should be initiated. Time 2 (t_2) signals when seizures may cause long-term consequences (e.g. neuronal injury and death, neuronal network impairment) and spans between 30 and >60 minutes depending on the type of SE as per t_1.[2]

Refractory SE (RSE) is defined as seizures persisting beyond 30–60 minutes despite appropriate doses of two anti-seizure medications (ASMs) and requires general anaesthetic drugs. RSE develops in about 20% of patients with SE. Continuation or recurrence of RSE beyond 24 hours of general anaesthetic therapy is defined as super RSE (SRSE) (Fig. 61.1).

The schematic representation outlines seizure management from onset to more than 24 hours. A timeline at the top with labelled magnetic resonance imaging scans runs from 5 to 10 minutes: brain injury, 10 to 30 minutes: Structural abnormalities versus Cryptogenic S E, 30 to 60 minutes: increased perfusion with hypervascularisation and vasodilation, more than 24 hours: restricted diffusion, cytotoxic and vasogenic brain oedema, brain-blood barrier breakdown, and 4 years: Chronic abnormalities such as brain atrophy, increased V P ratio, thalamic atrophy, gliosis, cortical necrosis. Each time band includes structured columns detailing clinical focus, investigations, interventions, and monitoring. The stages begin with initial recognition, followed by emergency treatment, refractory phases, and super-refractory care. The schematic also marks testing protocols, seizure types, and goals for intervention at each stage. The timeline is further categorised for different states of status epilepticus. 5 to 10 minutes as impending status epilepticus, 10 to 30 minutes as established status epilepticus, 30 to 60 minutes as refractory status epilepticus, more than 24 hours as super-refractory status epilepticus, and 4 years as long-term.

FIG. 61.1 Schematic representation of the evolution of status epilepticus and its imaging findings, cellular and molecular changes, systemic and cerebral pathophysiology, treatment choices, and electroencephalographic and clinical endpoints.

SE is classified according to semiology of seizures (Box 61.1), aetiology, electroencephalography (EEG) correlates and age. Key clinical features include history of previous seizures, presence and characteristics of motor symptoms and the degree of impairment of consciousness. Patients with SE can be either admitted to ICU because of ongoing SE as the primary diagnosis, or SE is diagnosed in ICU patients admitted with other diagnoses. Clinical subtypes commonly encountered in an intensive care unit (ICU) include: convulsive SE (CSE), non-convulsive SE (NCSE) with coma and myoclonic SE (MSE) with coma.

Box 61.1

Semiology of SE: Classification of SE by the International League Against Epilepsy (ILAE)

A. With prominent motor symptoms
  a. Convulsive SE (CSE) or tonic-clonic SE
    i. Generalised convulsive SE
    ii. Focal onset evolving into bilateral convulsive SE
    iii. Unknown onset SE (whether focal or generalised)
  b. Myoclonic SE (MSE)
    i. With coma

    ii. Without coma
  c. Focal motor SE (FMSE)
    i. Repeated focal motor seizures
    ii. Epilepsia partialis continua
    iii. Adversive SE
    iv. Oculoclonic SE
    v. Ictal paresis
  d. Tonic SE (TSE)
  e. Hyperkinetic SE (HSE)
B. Without prominent motor symptoms
  a. NCSE with coma (including 'subtle' SE)
  b. NCSE without coma
    i. Generalised
      1. Typical absence SE
      2. Atypical absence SE
      3. Myoclonic absence SE
    ii. Focal
      1. Without impairment of consciousness
      2. Aphasic SE
      3. With impaired consciousness
    iii. Unknown whether focal or generalised
      1. Autonomic SE

Aetiology and pathophysiology

Aetiology is one of the most important prognostic factors in SE. The most known causes of SE are structural lesions in the central nervous system (CNS), followed by metabolic, and systemic or local infectious causes (approximately 60% of presentations of CSE and NCSE). [1] , [2] Uncommon causes include immunological disorders, mitochondrial diseases, genetic disorders and toxins.[3] Some aetiologies are more likely to present in certain age ranges, such as stroke in the elderly population and mitochondrial and genetic disorders in the young. Depending on the temporal relationship with the primary insult, SE can be referred to as acute, remote or progressive.[4] Acute and remote SE refer to symptoms presenting either immediately (within one week) of a causal insult (e.g. stroke, brain trauma, encephalopathy and brain surgery) or following a precipitating factor in the context of an existing CNS disorder (e.g. withdrawal of anticonvulsants in people with epilepsy, previous stroke and brain space-occupying lesions). Progressive presentation of SE is more common in genetic, mitochondrial and prion encephalopathies.

Rarely, SE has been associated with drug toxicity following administration of anticonvulsants such as lamotrigine, antimicrobials such as beta-lactams, cephalosporins and quinolones, and chemotherapies/immunotherapies.[5–7]

Unfortunately, in almost half of the patients presenting with SE no underlying cause can be found on anatomical neuroimaging and laboratory tests. New-onset refractory status epilepticus (NORSE) describes RSE without a clear underlying cause (i.e. ‘cryptogenic NORSE’) despite extensive investigations and is one of the most severe types of SE.[8,9] Possible aetiologies of SE are listed in Table 61.1 .[1–3,10,11]

Table 61.1

Causes of SE in adults

AETIOLOGY	CAUSES/PRECIPITATING FACTORS
Prior epilepsy	Alcohol use or withdrawal Lack of compliance with ASMs Sleep deprivation Precipitating systemic or neurological illness
Cerebrovascular disease	Acute ischaemic stroke Subarachnoid haemorrhage Intracerebral haemorrhage Posterior reversible encephalopathy syndrome (PRES) Eclampsia Cerebral sinus venous thrombosis (CSVT)
Brain tumours	Gliomas, benign space-occupying lesions, lymphomas and brain metastases
Brain injury and neurodegenerative diseases	Traumatic brain injury Hypoxic-ischaemic brain injury Alzheimer's disease and other dementia syndromes
Electrolyte and metabolic disorders	Electrolyte abnormalities (hyponatraemia, hypocalcaemia, hypomagnesaemia, hypophosphataemia) Hyperglycaemia or hypoglycaemia Organ failure (uraemia, hepatic encephalopathy) Metabolic disorders (porphyria, ornithine transcarbamylase deficiency)
Infection and inflammation	Viral (cytomegalovirus, herpes simplex virus, human immunodeficiency virus) Bacterial infections (typical bacterial meningitis and abscesses, tuberculosis)

AETIOLOGY	CAUSES/PRECIPITATING FACTORS
	Parasitosis (toxoplasmosis, malaria, neurocysticercosis) Fungal infections (candidiasis, aspergillosis, coccidioidomycosis) Prionopathies Paraneoplastic encephalopathies
Intoxications	Alcohol – withdrawal or intoxication Drug toxicity – cephalosporins, isoniazid, tranexamic acid, tacrolimus, cyclosporine, tricyclic antidepressants, olanzapine, phenothiazines, theophylline, cocaine, amphetamine, anti-epileptic drugs, etc.
Genetic and autoimmune	Epilepsy syndromes (juvenile myoclonic epilepsy, Lennox-Gastaut Syndrome, Dravet Syndrome, etc.) Autoimmune encephalitis (anti-NMDA receptor encephalitis, anti-voltage-gated potassium channel receptor encephalitis, etc.) Systemic autoimmune disorders (cerebral lupus, thrombotic thrombocytopenic purpura, multiple sclerosis, Hashimoto's encephalopathy, etc.) Paraneoplastic encephalitis
Cryptogenic	New-onset refractory status epilepticus (NORSE)

SE and its refractory evolutions result from either the failure of normal seizure-terminating mechanisms or the initiation of mechanisms causing seizures to persist, or both.[2,12]

In healthy conditions, most of the CNS inhibitory modulation is gamma-aminobutyric acid (GABA) receptor-mediated. With ongoing seizure activity, GABA receptors undergo cellular internalisation and subsequent degradation, leading on one hand to the loss of endogenous inhibition and the persistence of seizures, and on the other to the progressive pharmacoresistance to GABAergic anticonvulsants, such as benzodiazepines. [12, 13]

Additionally, mechanisms that induce persistent seizures are predominantly excitatory via glutamine acting on *N*-methyl-D-aspartate (NMDA) receptors. NMDA receptors increase on synapses during ongoing epileptic activity, facilitating neuronal excitability and sustained seizures. This, in contrast, explains the efficacy of NMDA antagonists in refractory states.

The pathophysiological effects of seizures on the brain are thought to result from both direct excitotoxic neuronal injury and secondary injury owing to systemic complications, such as hypotension, hypoxia and hyperthermia. Ongoing excitation leads to neuronal injury and death, predominantly through intracellular calcium influx and mitochondrial dysfunction. [13]

Clinical characteristics

Convulsive Status Epilepticus

CSE is the most common and dangerous type of SE, and it presents with impaired consciousness and abnormal muscle contraction, which may be sustained (tonic) and/or interrupted (clonic) or both (tonic-clonic status epilepticus, TCSE). The seizures may be primarily generalised or have a focal onset evolving into bilateral convulsive SE. With time, the clinical manifestations may become subtle, and patients display only small amplitude twitching movements of the face, hands or feet or nystagmus (late or subtle CSE). Progressively, some patients will have no observable motor activity and the detection of ongoing seizures requires EEG. Most authors classify these subtle or electrical forms as NCSE. [14, 15]

Non-Convulsive Status Epilepticus With Coma

Until recently, the diagnosis of NCSE encompassed all SE of various aetiology where electroencephalography seizures are present in the absence of a clinical manifestation. To address the lack of a NCSE definition, in 2013 a consensus panel developed the so-called Salzburg working criteria for the electroclinical diagnosis of NCSE in comatose patients (Box 61.2) that have been validated in retrospective cohorts including critically ill patients.[16–21]

Box 61.2

Salzburg criteria for the diagnosis of NCSE

A. Epileptiform discharges >2.5 Hz, *or*
B. Epileptiform discharges ≤2.5 Hz or rhythmic delta/theta activity (>0.5 Hz) AND one of the following:
  a. EEG and clinical improvement after intravenous anti-epileptic drugs (ASMs), *or*
  b. Subtle clinical ictal phenomena during the EEG patterns mentioned above, *or*
  c. Typical spatiotemporal evolution (i.e. incrementing voltage and change in frequency, or evolution in pattern (change in frequency or change in topography), or decrementing termination (i.e. decrementing voltage or frequency)

From Beniczky S, Hirsch LJ, Kaplan PW, et al. Unified EEG terminology and criteria for nonconvulsive status epilepticus. *Epilepsia* . 2013;54(Suppl 6):28-29. doi: 10.1111/epi.12270 .

NCSE can be classified based on the presence or not of consciousness (with or without coma/stupor), onset type (generalised onset, focal onset or unknown onset), aetiology (symptomatic if known aetiology, or cryptogenic if unknown).[16]

NCSE should be suspected in any patient with an unexplained altered conscious state, particularly those with CNS injury, metabolic disturbance, hepatic encephalopathy or sepsis. Its incidence is probably underestimated because of lack of electroencephalography (EEG) resources to diagnose the condition.

Clinically, NCSE may be mistaken for other conditions, such as persisting sedative effects, metabolic encephalopathy and post-ictal confusion. A high index of suspicion must therefore be present to trigger electrodiagnostic investigation. NCSE is present in 14% to 34% of patients with CSE who do not recover consciousness after resolution of overt convulsive activity.[14,22]

Myoclonic Status Epilepticus With Coma

MSE is a type of SE with motor presentation characterised by a prolonged period of spontaneous myoclonic jerks, and in critically ill patients is often associated with hypoxic-ischaemic brain injury (HIBI) following cardiac arrest, toxic and metabolic encephalopathies and certain genetic epilepsy syndromes. MSE could present with preserved consciousness (primary or secondary MSE) with altered consciousness (in neurodegenerative diseases, in infectious or inflammatory diseases or in toxic-metabolic encephalopathies) or with coma (more commonly in HIBI).[23–28]

The clinical features of MSE often depend on the aetiology. Most cases of MSE encountered in critically ill patients present with altered consciousness or coma, myoclonic jerks are usually irregular and asynchronous, involving both proximal and distal muscle groups. In HIBI motor symptoms usually start the first or second day after cardiac arrest and persist for up to 7 days involving preferentially facial muscles with increased intensity after stimulation. In patients receiving muscle relaxants, EEG correlates might be present without motor symptoms.[26,27,29]

In the early phase after HIBI, it can be difficult to distinguish post-anoxic MSE, usually a poor prognostic indicator, from early presentation of Lance Adams Syndrome. The latter is characterised by chronic reflex myoclonus (usually late onset, days to weeks after cardiac arrest and persistence for months to years) without alterations of consciousness and is associated with a good neurological outcome.[28,30]

Clinical assessment and diagnostic tests

On initial assessment, an accurate history should be obtained, with particular emphasis on eyewitness accounts of the onset and semiology of the seizures, and a full physical examination performed. Neither should delay the initial management. Rapid control of seizures is crucial to prevent brain injury and the development of RSE. There is evidence that the longer SE goes untreated the harder it is to control with drugs.[13,31]

Neuroimaging and electroencephalography remain the key diagnostic tests to identify structural causes and either the presence of non-convulsive electrographical seizures or the electroclinical correlates of CSE/MSE.

Systemic Effects of SE

Amongst the systemic effects of SE, hypoxia and respiratory acidosis often follow acute seizures due to impaired ventilation and increased oxygen demand by prolonged muscle activation. In turn, hypoxia causes a mismatch in brain oxygen demand and supply, with hypoxic neuronal injury evident within 30–60 minutes after SE onset in the most vulnerable areas of the brain. The acidaemia due to respiratory acidosis is worsened by metabolic acidosis caused by the accumulation of lactate.[32,33]

Early in CSE, there is a marked increase in plasma catecholamines, producing systemic physiological changes (hypertension, tachycardia and cardiac arrhythmias) that resolve if SE is stopped early. If seizures continue patients can experience systemic hypotension and that may exacerbate neurological injury. In the most refractory forms of SE, ASMs and anaesthetic therapy might contribute to cardiovascular dysfunction via cardiotoxicity (lamotrigine, phenobarbital and pentobarbital) or cardiac failure (propofol infusion syndrome).[33–35]

Respiratory complications can arise because of worsening respiratory muscle dysfunction due to ongoing seizures, due to depression of the respiratory drive by certain ASMs and anaesthetic drugs, and finally due to respiratory tract infections following impaired airway protection and aspiration. It is estimated that almost a quarter of SE patients admitted to

ICU will develop a secondary severe systemic infection, and more than 90% of these involve the respiratory tract.[36]

Another complication of ongoing muscle contractions during seizures that is often reported in CSE is rhabdomyolysis which could lead to myoglobinuria and acute tubular necrosis and acute renal failure.[37]

Hyperthermia is owing to both muscle activity and central sympathetic drive and thus may still occur when paralysing agents prevent motor activity.[37] In early SE, both cerebral metabolic demand and cerebral blood flow (CBF) are increased. In late SE, although cerebral metabolic activity remains high, CBF may fall owing to hypotension and loss of cerebral autoregulation leading to cerebral ischaemia.[32]

Electroencephalography

The primary indication for intermittent and continuous EEG monitoring in critically ill patients is the identification of non-convulsive seizures, NCSE in patients with altered mental state and therapeutic monitoring in the most refractory cases (RSE and SRSE) (Fig. 61.2).[38,39] Case series where EEG has been performed in critically ill patients with an unexplained depressed conscious state have found a high incidence of non-convulsive seizures (8%–38%).[40–42] Electroencephalographic seizures are usually defined as continuous rhythmic or periodic epileptiform discharges at >2.5 Hz, or with frequency, morphology or location evolution, lasting at least 10 seconds.[16] However, in critically ill patients, these features are often different with similarities to the interictal features; periodic patterns or epileptiform discharges >2.5 Hz are considered ictal and <1 Hz as non-ictal. Features between 1 and 2.5 Hz represent the ictal-interictal continuum and their interpretation requires clinical correlation.[43,44] Very often, a trial of ASMS (such as benzodiazepines) is required to distinguish between ictal and interictal activity.

The prolonged electroencephalogram recording has six panels, labelled 1 to 5, depicting myoclonic status epilepticus after cardiac arrest and hypoxic ischemic encephalopathy. Raw and quantitative electroencephalogram recordings appear at different time points. The recordings display generalised periodic discharges, reduction of amplitude and frequency after midazolam, burst suppression after thiopental, and changes in suppression intervals with reappearance of sharp waves and epileptiform discharges. An additional panel provides a summarised view of the five panels.

FIG. 61.2 Prolonged EEG recording in a case of myoclonic status epilepticus following out of hospital cardiac arrest and hypoxic-ischaemic encephalopathy. Raw and quantitative EEG (QEEG) are shown at different timepoints. 1. Raw EEG shows generalised period discharges despite propofol, midazolam and fentanyl infusion. 2. A bolus of midazolam is administered with a reduction in the overall amplitude, and frequency of the persistent generalised period discharges. 3. A bolus of thiopental is given. 4. After two minutes the EEG shows burst suppression. There is an overall decrease in EEG amplitude and rhythmicity in the faster frequency bands as seen on the QEEG. 5. 10 minutes after the thiopental bolus has been given, the suppression intervals decrease in length and the bursts show reappearance of sharp-waves/epileptiform discharges.

Although recent evidence demonstrates that continuous EEG monitoring does not improve mortality and neurological outcomes compared to intermittent short EEG recordings, continuous recordings lead to more therapeutic changes.[45], [46] The impact of treatment adjustment on outcomes in critically ill patients remains unclear. Longer recordings (24–72 hours) show higher sensitivity in identifying seizures; however, the availability of continuous EEG in specialised units has been associated with increased interhospital transfer and could impact ICU occupancy rates.[47], [48] Because epileptiform abnormalities detected within the first 30 minutes of EEG monitoring in critically ill represent a risk factor for underlying seizures, a pragmatic assessment of these patients may include a short EEG performed at a non-specialised centre before considering transfer to a neurosciences unit.[41], [49]

Neuroimaging

Computed tomography (CT) or magnetic resonance imaging (MRI) of the brain highlights both reversible and irreversible changes in patients with SE and is indicated to identify structural, diffusion and perfusion abnormalities at different stages of the clinical presentation. Structural abnormalities have been identified in more than 60% of patients with SE, which may reflect the changes associated with prolonged seizures (increased metabolism, lactic acidosis, hypoglycaemia, hypoxia, hyper- or hypoperfusion and inflammation) or the aetiology itself of SE (e.g. brain tumours, CNS infections, stroke and haemorrhage).[50] Frequently, the imaging abnormalities reflect the dynamic pathophysiological changes during the acute episode of SE and their aftermath, such as increased perfusion with hypervascularisation and vasodilation immediately after onset, restricted diffusion hours later, both cytotoxic and vasogenic brain oedema, and brain-blood barrier (BBB) breakdown.[51], [52] Up to two-thirds of patients with SE develop chronic abnormalities on neuroimaging, most frequently characterised by brain atrophy and increased ventricular-parenchyma ratio, thalamic atrophy, gliosis and cortical necrosis.[53]

CerebroSpinal Fluid Analysis

Patients with SE will undergo neuroimaging and EEG studies as routine diagnostics tests. Cerebrospinal fluid (CSF) analysis of routine parameters, markers of neuronal damage and immune parameters may be useful in the differential diagnosis of SE.[54]

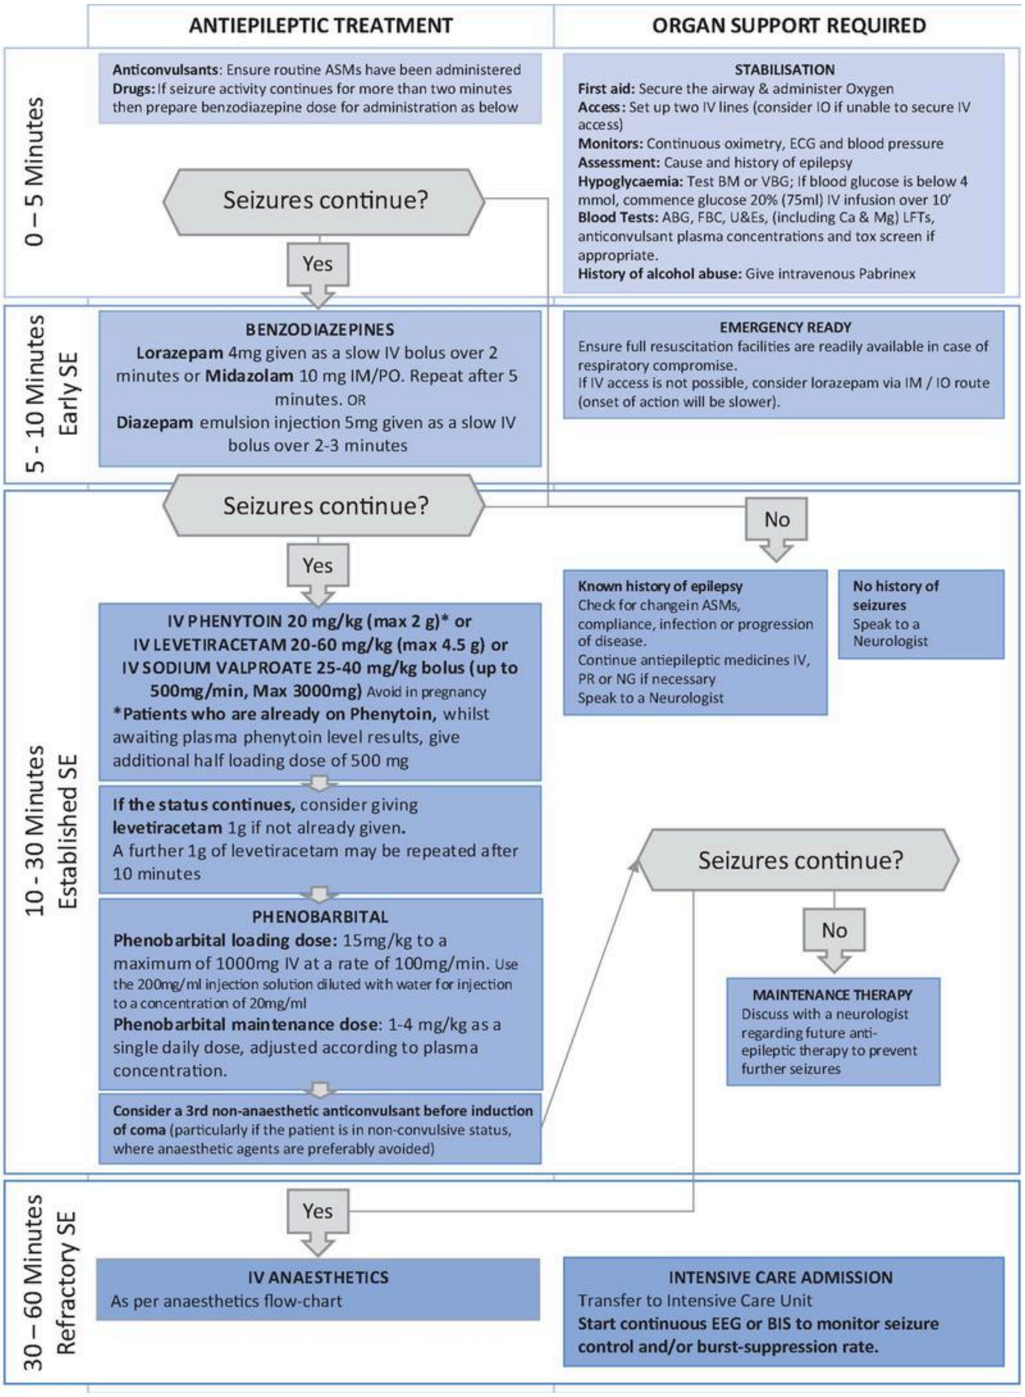
Routine parameters such as leukocyte cell count rarely demonstrate pleocytosis (4%–10%) and often reflect acute inflammation, but aid in the differential diagnosis with autoimmune or infectious meningo-encephalitis.[55], [56] CSF proteins are often elevated after seizures (10%–60%) but are non-specific as they reflect damage to the BBB rather than a specific aetiology. Likewise, CSF lactate is elevated in only 14%–28% of patients after seizures. The finding of elevated intrathecal immunoglobulins is rare (<10%), however, it can point towards the diagnosis of an autoimmune process. Markers of neuronal damage such as neuron-specific enolase and tau protein are often elevated in SE but their clinical and diagnostic significance is still unclear.[54,57]

In cases of suspected autoimmune aetiology, neuronal autoantibodies analysis in the CSF is essential, as well as CSF flow cytometry, which often shows an increase of CD8 T-lymphocytes in this population. Finally, abnormal cytokine levels such as interleukin-6 can be found in the CSF, however, their clinical significance remains unclear.[54,57]

Treatment

The management of SE encompasses the prompt termination of seizures, treating the precipitating causes and underlying conditions and the prevention of complications and recurrence of seizures. There is considerable debate as to whether NCSE presents the same degree of risk of neurological injury as CSE. Prompt treatment is generally recommended in all SE subtypes.[58]

The treatment of seizures is based on a tiered approach that follows the temporal progression of SE (Fig. 61.3).[15,58,59] After a very rapid vitals stabilisation and general assessment phase, the first-line seizure treatment includes parenteral administration of benzodiazepines, at repeated doses if necessary.[15,59] Failure to terminate seizures after 10–15 minutes warrants the initiation of a second-line treatment with ASMs. A recent randomised clinical trial (RCT) demonstrated similar efficacy between valproate sodium, phenytoin and levetiracetam at this stage.[60,61]



Anticonvulsants: Ensure routine ASMs have been administered
Drugs: If seizure activity continues for more than two minutes then prepare benzodiazepine dose for administration as below

STABILISATION
First aid: Secure the airway & administer Oxygen
Access: Set up two IV lines (consider IO if unable to secure IV access)
Monitors: Continuous oximetry, ECG and blood pressure
Assessment: Cause and history of epilepsy
Hypoglycaemia: Test BM or VBG; If blood glucose is below 4 mmol, commence glucose 20% (75ml) IV infusion over 10′
Blood Tests: ABG, FBC, U&Es, (including Ca & Mg) LFTs, anticonvulsant plasma concentrations and tox screen if appropriate.
History of alcohol abuse: Give intravenous Pabrinex

BENZODIAZEPINES
Lorazepam 4mg given as a slow IV bolus over 2 minutes or **Midazolam** 10 mg IM/PO. Repeat after 5 minutes. OR
Diazepam emulsion injection 5mg given as a slow IV bolus over 2-3 minutes

EMERGENCY READY
Ensure full resuscitation facilities are readily available in case of respiratory compromise.
If IV access is not possible, consider lorazepam via IM / IO route (onset of action will be slower).

IV PHENYTOIN 20 mg/kg (max 2 g)* or
IV LEVETIRACETAM 20-60 mg/kg (max 4.5 g) or
IV SODIUM VALPROATE 25-40 mg/kg bolus (up to 500mg/min, Max 3000mg) Avoid in pregnancy
***Patients who are already on Phenytoin,** whilst awaiting plasma phenytoin level results, give additional half loading dose of 500 mg

Known history of epilepsy
Check for changein ASMs, compliance, infection or progression of disease.
Continue antiepileptic medicines IV, PR or NG if necessary
Speak to a Neurologist

No history of seizures
Speak to a Neurologist

If the status continues, consider giving **levetiracetam** 1g if not already given.
A further 1g of levetiracetam may be repeated after 10 minutes

PHENOBARBITAL
Phenobarbital loading dose: 15mg/kg to a maximum of 1000mg IV at a rate of 100mg/min. Use the 200mg/ml injection solution diluted with water for injection to a concentration of 20mg/ml
Phenobarbital maintenance dose: 1-4 mg/kg as a single daily dose, adjusted according to plasma concentration.

MAINTENANCE THERAPY
Discuss with a neurologist regarding future anti-epileptic therapy to prevent further seizures

Consider a 3rd non-anaesthetic anticonvulsant before induction of coma (particularly if the patient is in non-convulsive status, where anaesthetic agents are preferably avoided)

IV ANAESTHETICS
As per anaesthetics flow-chart

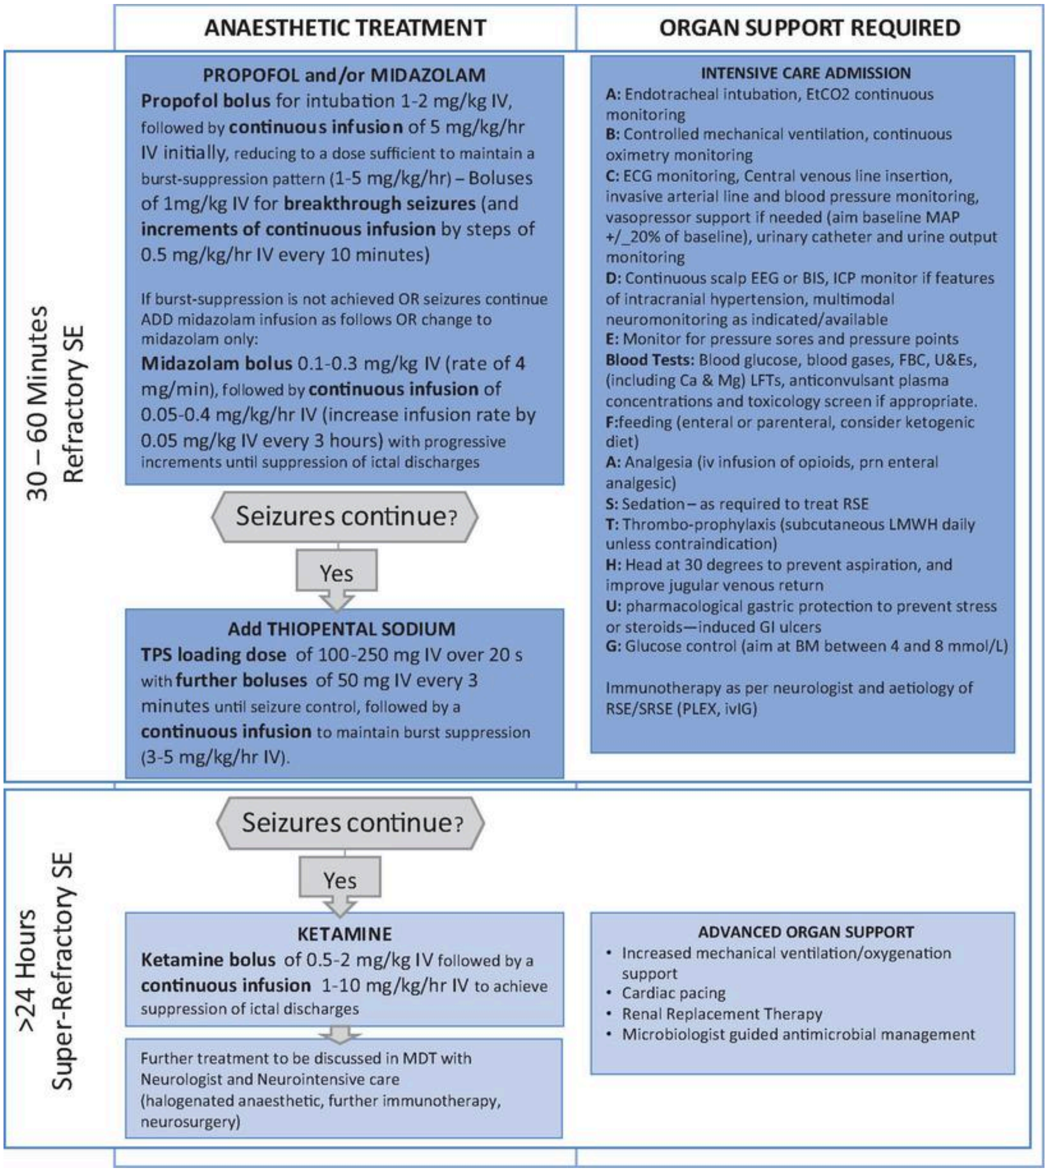
INTENSIVE CARE ADMISSION
Transfer to Intensive Care Unit
Start continuous EEG or BIS to monitor seizure control and/or burst-suppression rate.

The diagram outlines the decision path for antiseizure treatment and organ support within a 0 to 60 minute period. The left section lists treatment options starting with benzodiazepines, followed by antiseizure drugs such as levetiracetam, valproate sodium, and phenytoin. The right section includes supportive care such as airway support and vital monitoring. Each decision branch ends in a box querying whether seizures continue. Depending on the response, it directs to further antiseizure measures or escalation to anaesthetic treatment and organ support in the next stage.

FIG. 61.3 Protocol for the treatment of status epilepticus.

Notably, MSE due to idiopathic epilepsies usually responds to ASMs with specific antimyoclonic properties such as benzodiazepines, valproate and levetiracetam, but also zonisamide and piracetam. [62] On the other hand, there is a lack of agreement on the effectiveness of ASMs in MSE following circulatory arrest and treatment often follows the algorithm for CSE/NCSE. [63]

In cases of ongoing convulsive seizures, a second non-anaesthetising ASM is often added, but if after 30 minutes seizures remain refractory to treatment it is recommended to proceed to use general anaesthetic drugs, airway protection and transfer to ICU (Fig. 61.4). [13, 59] The side effects of aggressive treatment (hypotension, immobility, immunosuppression) need to be balanced against the potential neurological morbidity of SE and so treatment is tailored according to the aetiology. [64]



ANAESTHETIC TREATMENT

ORGAN SUPPORT REQUIRED

30 – 60 Minutes
Refractory SE

PROPOFOL and/or MIDAZOLAM

Propofol bolus for intubation 1-2 mg/kg IV, followed by **continuous infusion** of 5 mg/kg/hr IV initially, reducing to a dose sufficient to maintain a burst-suppression pattern (1-5 mg/kg/hr) – Boluses of 1mg/kg IV for **breakthrough seizures** (and **increments of continuous infusion** by steps of 0.5 mg/kg/hr IV every 10 minutes)

If burst-suppression is not achieved OR seizures continue ADD midazolam infusion as follows OR change to midazolam only:

Midazolam bolus 0.1-0.3 mg/kg IV (rate of 4 mg/min), followed by **continuous infusion** of 0.05-0.4 mg/kg/hr IV (increase infusion rate by 0.05 mg/kg IV every 3 hours) with progressive increments until suppression of ictal discharges

Seizures continue?

Yes

Add THIOPENTAL SODIUM

TPS loading dose of 100-250 mg IV over 20 s with **further boluses** of 50 mg IV every 3 minutes until seizure control, followed by a **continuous infusion** to maintain burst suppression (3-5 mg/kg/hr IV).

INTENSIVE CARE ADMISSION

A: Endotracheal intubation, EtCO2 continuous monitoring
B: Controlled mechanical ventilation, continuous oximetry monitoring
C: ECG monitoring, Central venous line insertion, invasive arterial line and blood pressure monitoring, vasopressor support if needed (aim baseline MAP +/_20% of baseline), urinary catheter and urine output monitoring
D: Continuous scalp EEG or BIS, ICP monitor if features of intracranial hypertension, multimodal neuromonitoring as indicated/available
E: Monitor for pressure sores and pressure points
Blood Tests: Blood glucose, blood gases, FBC, U&Es, (including Ca & Mg) LFTs, anticonvulsant plasma concentrations and toxicology screen if appropriate.
F:feeding (enteral or parenteral, consider ketogenic diet)
A: Analgesia (iv infusion of opioids, prn enteral analgesic)
S: Sedation – as required to treat RSE
T: Thrombo-prophylaxis (subcutaneous LMWH daily unless contraindication)
H: Head at 30 degrees to prevent aspiration, and improve jugular venous return
U: pharmacological gastric protection to prevent stress or steroids—induced GI ulcers
G: Glucose control (aim at BM between 4 and 8 mmol/L)

Immunotherapy as per neurologist and aetiology of RSE/SRSE (PLEX, ivIG)

>24 Hours
Super-Refractory SE

Seizures continue?

Yes

KETAMINE

Ketamine bolus of 0.5-2 mg/kg IV followed by a **continuous infusion** 1-10 mg/kg/hr IV to achieve suppression of ictal discharges

Further treatment to be discussed in MDT with Neurologist and Neurointensive care (halogenated anaesthetic, further immunotherapy, neurosurgery)

ADVANCED ORGAN SUPPORT

- Increased mechanical ventilation/oxygenation support
- Cardiac pacing
- Renal Replacement Therapy
- Microbiologist guided antimicrobial management

The schematic divides seizure treatment into two sections based on duration. The top section covers 30 to 60 minutes with anaesthetic agents such as propofol, midazolam, and thiopental sodium. The bottom section outlines care for seizures exceeding 24 hours, introducing ketamine and advanced organ support strategies. Each treatment option includes specific dosages and escalation guidance. On the right side, the organ support column includes ventilation, hemodynamic monitoring, and nutrition support. Each section concludes with decision boxes based on seizure persistence.

FIG. 61.4 Protocol for the treatment of refractory and super-refractory status epilepticus.

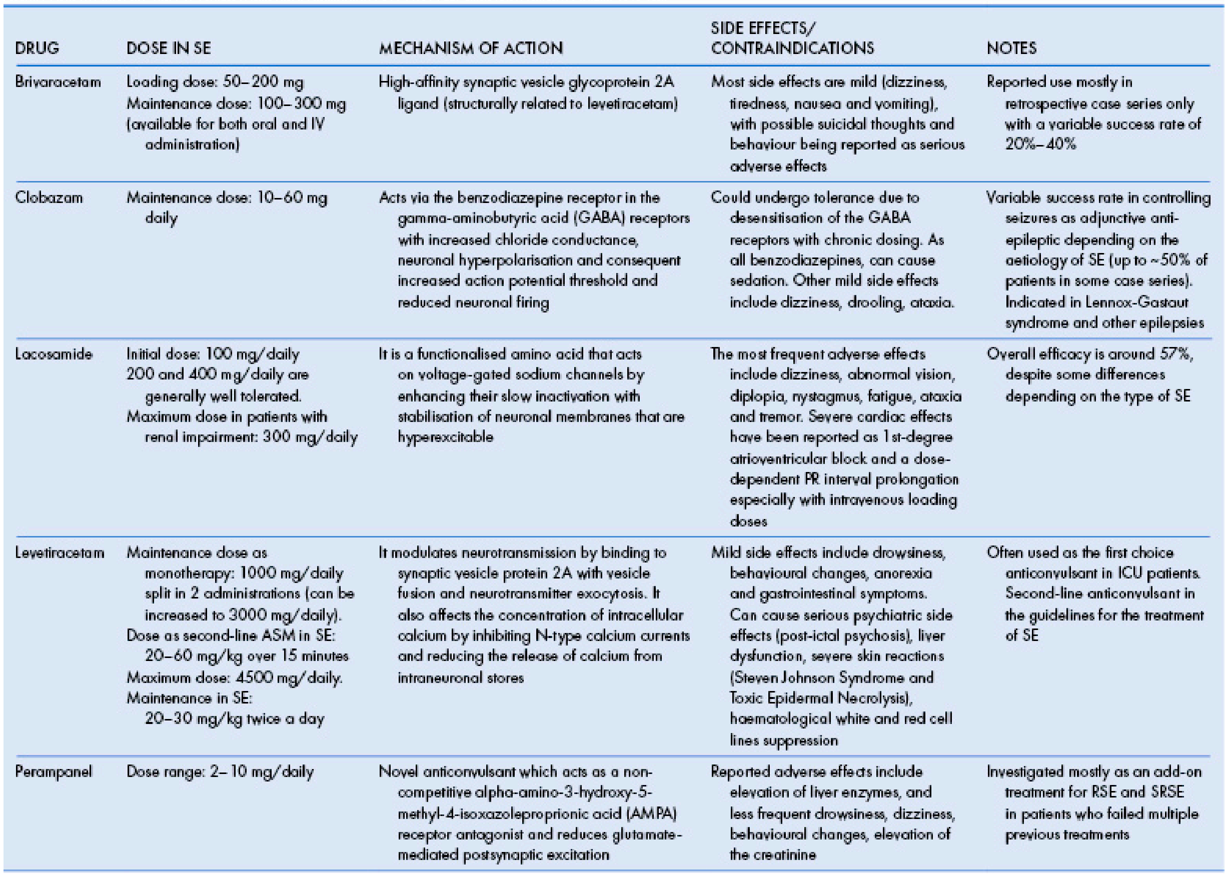
Evidence is limited to guide the treatment of RSE and SRSE, for which anaesthetic agents, such as propofol, midazolam, thiopental and ketamine infusions, are commonly used.[13, 31] A single RCT in RSE comparing propofol versus barbiturates showed no difference in clinical outcome but an increased rate of burst suppression on EEG in the barbiturate arm, although the study was terminated early due to slow recruitment.[65] Two RCTs planned to explore the effectiveness of ketamine and alternative ASMs have recently been stopped due to low recruitment (ClinicalTrials.gov IDs: NCT03115489 and NCT02726867), and a new RCT is planned to explore the effectiveness of perampanel in RSE (NCT05684978). Amongst the inhalational anaesthetics explored for the treatment of RSE, isoflurane has been successfully used to achieve burst suppression. However, no large RCT data are available and limitations to its use include difficulties with administration in intensive care due to lack of scavenging ports, high incidence of seizure recurrence on discontinuation and adverse effects (e.g. hypotension and ileus), including concerns about neurotoxicity.[66]

The EEG treatment endpoint in RSE and SRSE remains unclear, and existing guidelines recommend seizure suppression, followed by burst suppression (periods of high-voltage electrical activity ‘bursts’ alternating with periods of suppression) if seizures persist.[13, 31, 67]

Adjuncts to general anaesthetics include magnesium infusion, and additional ASMs such as lacosamide, topiramate, phenobarbital, brivaracetam and perampanel (Table 61.2).[31, 68–70]

Table 61.2

Non-anaesthetising anti-seizure medicaitons (ASMs) commonly used in SE listed alphabetically



DRUG	DOSE IN SE	MECHANISM OF ACTION	SIDE EFFECTS/ CONTRAINDICATIONS	NOTES
Brivaracetam	Loading dose: 50–200 mg Maintenance dose: 100–300 mg (available for both oral and IV administration)	High-affinity synaptic vesicle glycoprotein 2A ligand (structurally related to levetiracetam)	Most side effects are mild (dizziness, tiredness, nausea and vomiting), with possible suicidal thoughts and behaviour being reported as serious adverse effects	Reported use mostly in retrospective case series only with a variable success rate of 20%–40%
Clobazam	Maintenance dose: 10–60 mg daily	Acts via the benzodiazepine receptor in the gamma-aminobutyric acid (GABA) receptors with increased chloride conductance, neuronal hyperpolarisation and consequent increased action potential threshold and reduced neuronal firing	Could undergo tolerance due to desensitisation of the GABA receptors with chronic dosing. As all benzodiazepines, can cause sedation. Other mild side effects include dizziness, drooling, ataxia.	Variable success rate in controlling seizures as adjunctive anti-epileptic depending on the aetiology of SE (up to ~50% of patients in some case series). Indicated in Lennox-Gastaut syndrome and other epilepsies
Lacosamide	Initial dose: 100 mg/daily 200 and 400 mg/daily are generally well tolerated. Maximum dose in patients with renal impairment: 300 mg/daily	It is a functionalised amino acid that acts on voltage-gated sodium channels by enhancing their slow inactivation with stabilisation of neuronal membranes that are hyperexcitable	The most frequent adverse effects include dizziness, abnormal vision, diplopia, nystagmus, fatigue, ataxia and tremor. Severe cardiac effects have been reported as 1st-degree atrioventricular block and a dose-dependent PR interval prolongation especially with intravenous loading doses	Overall efficacy is around 57%, despite some differences depending on the type of SE
Levetiracetam	Maintenance dose as monotherapy: 1000 mg/daily split in 2 administrations (can be increased to 3000 mg/daily). Dose as second-line ASM in SE: 20–60 mg/kg over 15 minutes Maximum dose: 4500 mg/daily. Maintenance in SE: 20–30 mg/kg twice a day	It modulates neurotransmission by binding to synaptic vesicle protein 2A with vesicle fusion and neurotransmitter exocytosis. It also affects the concentration of intracellular calcium by inhibiting N-type calcium currents and reducing the release of calcium from intraneuronal stores	Mild side effects include drowsiness, behavioural changes, anorexia and gastrointestinal symptoms. Can cause serious psychiatric side effects (post-ictal psychosis), liver dysfunction, severe skin reactions (Steven Johnson Syndrome and Toxic Epidermal Necrolysis), haematological white and red cell lines suppression	Often used as the first choice anticonvulsant in ICU patients. Second-line anticonvulsant in the guidelines for the treatment of SE
Perampanel	Dose range: 2–10 mg/daily	Novel anticonvulsant which acts as a non-competitive alpha-amino-3-hydroxy-5-methyl-4-isoxazoleproprionic acid (AMPA) receptor antagonist and reduces glutamate-mediated postsynaptic excitation	Reported adverse effects include elevation of liver enzymes, and less frequent drowsiness, dizziness, behavioural changes, elevation of the creatinine	Investigated mostly as an add-on treatment for RSE and SRSE in patients who failed multiple previous treatments

Neuromuscular-blocking agents are indicated if uncontrolled motor activity causes difficulty with providing adequate ventilation or severe lactic acidosis. Paralysis should be used only if EEG monitoring is available as the clinical expression of seizure activity is abolished.

Although hypothermia (32–34°C) has not been shown to improve outcomes in CSE, it could be effective in the treatment of RSE and SRSE as adjuvant to ASMs and anaesthetic therapy.[71] Targeted temperature management with avoidance of fever as a general neuroprotective strategy is advised in neurocritical care patients, and similar recommendations could be applied to RSE and SRSE patients.[72, 73]

Immunotherapy (high-dose steroids, immunoglobulins and/or plasma exchange) is used in SRSE from paraneoplastic aetiologies or autoimmune encephalitis and is recommended in the treatment algorithm for cryptogenic RSE.[70, 74]

Although ketogenic diet has a place in the existing recommendations for the treatment of NORSE and SRSE, it is rarely used in adults due to the perceived lack of efficacy, difficulty in achieving ketosis and gaps in high-quality supportive evidence.[74, 75]

Finally, in selected cases of RSE surgery shows promising results.[69] Techniques include focal cortical resection, multiple subpial transection, corpus callosotomy, hemispherectomy and vagus nerve stimulation.[59, 69]

Prognosis

SE is associated with low to severe functional disability, and a mortality of 10%–20% that reaches 40% and 80% in RSE and SRSE, respectively.[10, 13, 76] MSE following cardiac arrest is characterised by very poor functional outcome and mortality up to 90%.[77]

Reversible causes of SE, such as low ASM levels and alcohol withdrawal, are associated with favourable outcomes. On the other hand, features often associated with poor outcomes after CSE include coma on presentation, older age, presence of brain damage, longer seizure duration, focal neurological signs on onset and refractory seizures.[1, 10] Factors predicting outcome in NCSE are more unclear and the use of prognostic scores such as Status epilepticus severity score (STESS). Epidemiology-based mortality score in status epilepticus (EMSE), and encephalitis, NCSE, diazepam resistance, imaging features and tracheal intubation score (END-IT) remain controversial in this population.[78–82]

In people without a prior history of epilepsy, the presence of SE with refractory seizures, and delayed 1st line treatment have been shown to be associated with seizure recurrence.[83] Although most survivors of SE demonstrate structural and functional brain abnormalities on follow-up imaging and neurophysiology exams, more research is required to explore the mechanisms of epileptogenesis following SE in non-epileptic patients.[84, 85]

Special circumstances

SE in Children

SE in children is a neurological emergency that warrants special considerations. Seizures and SE in the paediatric population are described in detail in Chapter 95 .

SE in the Elderly

Acute symptomatic SE is common in older adults owing to the increased incidence of brain tumours, neurodegenerative disorders and cerebrovascular disease compared to younger patients. [86] In addition to epidemiological differences, NCSE is often a diagnostic challenge in older patients, sometimes being hardly distinguishable from acute encephalopathy or fluctuating cognition. [87]

Despite these age-specific considerations, treatment in elderly patients often follows guidelines developed for a younger cohort, and large RCTs specifically designed to account for medical comorbidities and polypharmacy of the elderly population are lacking. [88] However, it seems potentially reasonable to attempt using a third non-sedating ASMs prior to proceeding to general anaesthesia in RSE.

SE in Pregnancy

SE is rare but has been associated with increased pregnancy-related mortality and adverse fetal outcomes in women with known epilepsy (WWE). [89] It is often caused by inadequate seizure control due to increased drug clearance in all trimesters, but most pronounced in the first trimester of pregnancy. [90] On the other hand, causes of new-onset SE in pregnancy (NOSEP) include eclampsia, posterior reversible encephalopathy syndrome, cortical venous thrombosis, subarachnoid haemorrhage and autoimmune encephalitis. [91,92] It is important to involve a multidisciplinary team including a neonatologist, midwives, obstetrician and neurologist to diagnose and treat both NOSEP and SE in WWE as well as consider termination of pregnancy or induction of labour and delivery. Magnesium is the drug of choice in eclamptic seizures, and some ASMs such as valproate must be avoided especially in the first trimester due to the high risk of birth defects and developmental disorders. [93]

SE in Low-Resource Settings

Although SE is a major global health problem requiring prompt and aggressive treatment, most of the drugs recommended in guidelines and protocols are not readily available in low-resource settings. [94] In these settings, modifications to the traditional guidelines are recommended. For example, diazepam is a valid alternative as the first-line treatment instead of lorazepam, and trialling ketamine before GABAergic anaesthetising agents such as propofol, midazolam and thiopental sodium could reduce the requirement for intubation and mechanical ventilation. [95–97] Additionally, amongst the general anaesthetic drugs, propofol is recommended over thiopental sodium due to its ability to terminate seizures effectively and shorter context-sensitive half-life. [97], [98]

Acute cerebrovascular complications

Thearina de Beer

Cerebrovascular disease is common and its acute manifestation, stroke, produces considerable morbidity and mortality. Stroke is defined as an acute focal neurological deficit caused by cerebrovascular disease, which lasts for more than 24 hours or causes death before 24 hours. Transient ischaemic attack (TIA) also causes focal neurology, but this resolves within 24 hours. Stroke is the fourth largest cause of death in the United Kingdom, the second largest worldwide and is the most common cause of physical disability in adults. [1] Stroke can be categorised as ischaemic or haemorrhagic (Table 62.1).

Table 62.1

The main risk factors are increasing age, hypertension, ischaemic heart disease, atrial fibrillation, smoking, diabetes, obesity, some oral contraceptives, raised cholesterol or haematocrit and latterly SARS-CoV2 infection.

Prognosis in Acute Cerebrovascular Disease

Mortality after stroke averages 16%–23% within a month, with more patients dying after subarachnoid haemorrhage (SAH) or intracerebral haemorrhage than after cerebral infarction. In all types of stroke, about 30% of survivors remain disabled to the point of being dependent on others. Risk of stroke increases with age and doubles every decade over the age of 55.[1] Stroke should be regarded as a medical emergency. Patients should initially be treated in a stroke unit as there is good evidence of a reduction in both mortality and dependency compared with those treated in a general ward.[2]

Cerebral Infarction

Infarction of cerebral tissue (ischaemic stroke) occurs as a result of inadequate perfusion from occlusion of cerebral blood vessels (large or small) in association with inadequate collateral circulation. It may occur due to cerebral thrombosis or embolism.

Aetiology and Pathology

Cerebral Thrombosis

Atherosclerosis causes major arterial occlusion and most often produces symptoms if it occurs at the bifurcation of the carotid artery or the carotid siphon. Progressive plaque formation causes narrowing and forms a nidus for platelet aggregation and thrombus formation. Ulceration and rupture of the plaque expose its thrombogenic lipid core, activating the clotting cascade. Hypertension and diabetes mellitus are common causes of smaller arterial thrombosis. Rarer causes include any disease resulting in vasculitis, vertebral or carotid artery dissection (either spontaneous or post-traumatic) or carotid occlusion by strangulation or systemic hypotension after cardiac arrest. Cerebral venous thrombosis, responsible for less than 1% of strokes, may occur in hypercoagulable states, such as dehydration, polycythaemia, thrombocythaemia, some oral contraceptive pills, protein C or S deficiency, or antithrombin III deficiency or vessel occlusion by tumour or abscess. Latterly, SARS-CoV2 infections requiring ICU can cause thrombosis, the incidence seems to be between 2% and 3.9% and usually causes large vessel disease.[3], [4] Cerebral infarction may also result from sustained systemic hypotension from any cause, particularly if associated with hypoxaemia.

Cerebral Embolism

Embolism commonly occurs from thrombus or platelet aggregations overlying arterial atherosclerotic plaques, but 30% of cerebral emboli will arise from thrombus in the left atrium or ventricle of the heart. This is very likely in the presence of atrial fibrillation, left-sided valvular disease (infective endocarditis), recent myocardial infarction, chronic atrial enlargement or ventricular aneurysm. The presence of a patent foramen ovale or septal defects allows paradoxical embolism to occur. Iatrogenic air embolism may occur during cardiopulmonary bypass, can be central venous catheter-associated (usually removal), or as a result of cardiac catheterisation or cerebral angiography. Embolisation may also occur as a complication of attempted coil embolisation of cerebral aneurysms or arteriovenous malformations (AVMs) after SAH.

Clinical Presentation

In cerebral thrombosis, there is initially no loss of consciousness or headache, and the initial neurological deficit develops over several hours. Cerebral embolism may be characterised by sudden onset and rapid development of complete neurological deficits. No single clinical sign or symptom can reliably distinguish a thrombotic from an embolic event.

Where infarction occurs in a limited arterial territory the clinical signs are often characteristic. Infarction of the middle cerebral territory leads to dense contralateral hemiplegia, contralateral facial paralysis, contralateral hemianopia and ipsilateral eye deviation. Dominant left-hemisphere lesions result in language difficulties from aphasia, dysphasia, dysgraphia and dyscalculia. Non-dominant right hemispheric lesions cause the patient to neglect the left side, and failure to communicate with anyone approaching from that side. In strokes involving the posterior fossa, the precise pattern of symptoms depends on the arterial territories involved and the presence or absence of collaterals. The onset of symptoms, such as gait disturbance, headache, nausea, vomiting and loss of consciousness, may be very rapid. Venous thrombosis may occur, particularly in the cerebral veins, sagittal or transverse dural sinuses, causing headache, seizures, focal neurology and loss of consciousness. Other cognitive effects of stroke include memory impairment, anxiety, depression, emotional lability, aprosody and spatial impairment. Bilateral brainstem infarction after basilar artery thrombosis may produce deep coma and tetraparesis. Pontine stroke may produce ‘locked-in’ syndrome. The precise clinical presentation depends on the size of the infarcted area and its position in the brain. Vascular lesions, such as carotid dissection, can present with ipsilateral Horner syndrome with facial pain, a painful Horner’s from local stellate ganglion damage or if there is significant ischaemia from impaired flow or emboli, then with contralateral signs consistent with infarction. [5]

Investigations

A full history and examination of the patient will produce a differential diagnosis that will require specific investigations. The aim is to make the diagnosis, establish the nature, size and position of the pathology, so that correct treatment can target the effects of the primary injury, and prevent extension of the lesion or complications occurring.

Blood Tests for Stroke Patients

See Table 62.2

Table 62.2

Blood tests for stroke patients

Blood glucose to exclude diabetes and hypoglycaemia	Cardiac enzymes and troponin should be taken after an electrocardiogram (ECG)
Full blood count to exclude polycythaemia, infection and thrombocythaemia	Urea and electrolytes and liver function tests to rule out a metabolic reason for symptoms
Sickle cell test to exclude sickle cell disease	Coagulation screen specific investigation for thrombophilia due to protein C, protein S, Leiden factor V and antithrombin III, abnormalities should be undertaken in patients with venous thrombosis or patients with otherwise unexplained cerebral infarction or TIA
Heparin-induced thrombocytopaenia (HIT) to exclude HIT in patients at risk of HIT	Homocysteine level to exclude homocystinuria
ESR if raised could be vasculitis, infection or carcinoma	Serum cholesterol triglyceride as risk factors for stroke
C-reactive protein if raised could be vasculitis, infection or carcinoma	Syphilis serology to exclude as a cause of stroke
Blood cultures may diagnose infective causes, such as subacute	Pregnancy test on females under the age of 55

bacterial endocarditis	

Viral Swabs

Using PCR testing for SARS-CoV2 infection is considered the gold standard for the diagnosis of COVID-19 infection. The risk of stroke in COVID-19 infection seems to increase with the severity of the illness but occurs in younger patients and carries a higher mortality than non-COVID-19 stroke. [6]

Electrocardiography

This may demonstrate atrial fibrillation, other arrhythmias or a recent myocardial infarct.

Echocardiography

Either transthoracic or transoesophageal echocardiography (TOE) may demonstrate mural or atrial appendage thrombus as a source of embolism. TOE is more effective in detecting patent foramen ovale, aortic arteriosclerosis, vegetations or dissection. The decision to perform echocardiography should be based on history, ECG or examination findings. [2]

Imaging

Guidelines suggest a computed tomography (CT) brain scan within 1 hour of presentation for patients with a suspected stroke. [2] The imaging is used to distinguish infarction from haemorrhage. Tumour, abscess or subdural haematoma may also produce the symptoms and signs of stroke. Early scanning is vital if interventional treatment, such as thrombolysis, thrombectomy, anticoagulation, antiplatelet therapy or surgery, is planned.

The CT scan may be normal or show only minor loss of grey/white matter differentiation in the first 24 hours after ischaemic stroke, but haemorrhage is seen as areas of increased attenuation within minutes. CT angiography (CTA) will often demonstrate vascular abnormalities and vasospasm but multimodal magnetic resonance imaging (MRI), a combination of diffusion and perfusion-weighted MRI and magnetic resonance angiography (MRA), is much more sensitive in demonstrating small areas of ischaemia. Timing from the onset of symptoms and the exclusion of intracranial haemorrhage (ICH) determines the suitability and benefit of thrombolysis. [7] Where cerebral infarction has occurred as a result of venous thrombosis, the best imaging technique is MRA, but a CT venogram (CTV) may expedite diagnosis to thrombolyse or proceed to mechanical thrombectomy where indicated. Any patient with a stroke or TIA in the internal carotid artery territory should have duplex Doppler ultrasonography, which may demonstrate stenosis, occlusion or dissection of the internal carotid. Where trauma is an aetiological factor reconstruction CT bone window views are required to demonstrate any site of fracture-associated vascular injury.

Management

There is strong evidence that admission to a specialised stroke care unit as soon as possible after the occurrence of a stroke provides a cost-effective reduction in long-term damage to the brain and disability. [2]

Airway and Breathing

Patients with a Glasgow Coma Score (GCS) of 8 or less, or those with an absent gag reflex or defects of swallowing (both of which may occur at higher GCS), will require intubation to protect the airway and to prevent aspiration. Where this requirement is likely to be prolonged, early tracheostomy should be considered. An oxygen saturation of 95% or above [2] and supplemental oxygen are prescribed if the oxygen saturation falls below 95%. If hypercarbia occurs, then ventilatory support to achieve normocarbia is necessary to prevent exacerbation of cerebral oedema.

Circulatory Support

A large number of stroke patients will have raised blood pressure (BP) on admission, presumably as an attempt by the vasomotor centre to improve cerebral perfusion. Hypertensive patients may have impaired autoregulation and regional cerebral perfusion may be very dependent on BP. The patient’s clinical condition, neurological status and how the stroke was treated, should determine treatment for hypertension rather than an arbitrary level of BP. The American Stroke Association/American Heart Association (ASA/AHA) acute stroke guidelines recommend: (1) in patients with BP less than 220/120 mmHg who did not receive intravenous thrombolysis or endovascular treatment and had no comorbid conditions requiring acute antihypertensive therapy, the benefit of initiating or reinitiating treatment of hypertension within the first 48–72 h is uncertain. It might be reasonable to lower BP by 15% during the early phase (2) a BP less than 185/110 mm Hg in patients who are candidates for either intravenous thrombolysis or endovascular treatment. [8] The OPTIMAL-BP trial showed that a systolic BP of <140 mm Hg for the first 24 hours after endovascular treatment was detrimental to the outcome. A systolic BP of 140–180 mm Hg is advised in this scenario. [9] It would seem reasonable on physiological grounds to avoid antihypertensive drugs that cause cerebral vasodilatation in that they may aggravate cerebral oedema. Furthermore, it is more important to have controlled BP lowering than uncontrolled swings in BP. Cardiac output should be maintained and any underlying cardiac pathology, such as failure, infarction and atrial fibrillation, treated appropriately.

Metabolic Support

Both hypo- and hyperglycaemia have been shown to worsen prognosis after acute stroke; therefore blood sugar levels should be maintained in the normal range (4.4–9.9 mmol/L). [10] Early enteral feeding should be instituted by nasogastric (NG) intubation if needed; patients with posterior fossa strokes are at high risk of needing tracheostomy and NG feeding. In the longer term, particularly where bulbar function is reduced, percutaneous endoscopic or radiological gastrostomy may be necessary.

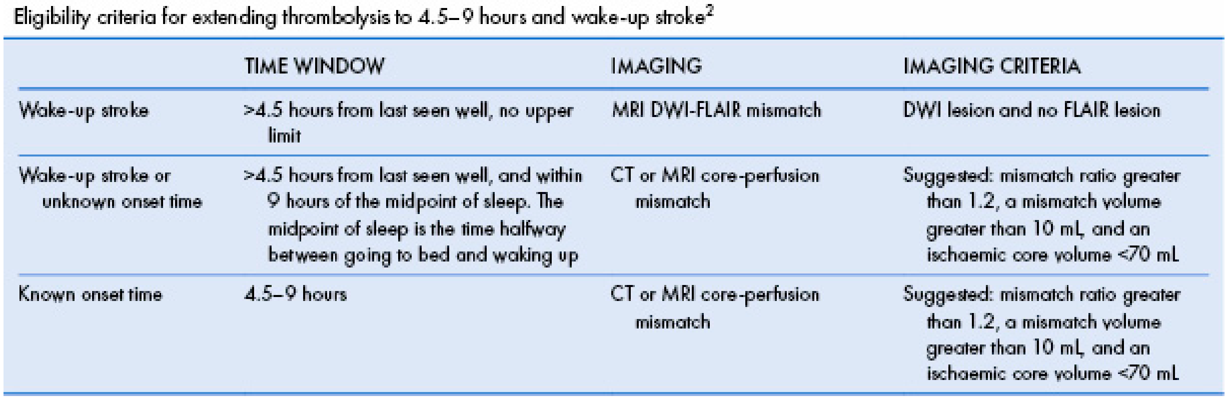
Anticoagulation

The routine use of prophylactic heparin in immobile stroke patients should be avoided as the risk of intracerebral bleeding is high. Only in cerebral venous thrombosis should anticoagulation be considered, initially heparin then warfarin (with an International Normalised Ratio (INR) target of 2–3) for 3 months. Intermittent pneumatic calf compression should be used for 30 days or until mobile. [2] Anticoagulation can only be recommended in individuals where there is a high risk of stroke recurrence, such as in those patients with prosthetic heart valves, atrial fibrillation with thrombus or those with thrombophilic disorders. A CT scan must be obtained prior to commencing therapy to exclude haemorrhage, and careful monitoring used. In patients with large infarcts, there is always the risk of haemorrhage (haemorrhagic transformation) into the infarct and early heparinisation is best avoided. Aspirin 300 mg per day should be given within 24–48 hours after thrombolysis and continued for 2 weeks while antithrombotic therapy is commenced. If the patient is intolerant of aspirin, an alternative, such as clopidogrel, should be used. [2]

Thrombolysis

Thrombolysis with intravenous recombinant tissue plasminogen activator (rtPA alteplase) is now an established treatment for acute ischaemic stroke within 4.5 hours of last seen well (LSW). There are also now criteria for thrombolysis if LSW is 4.5–9 hours and for ‘wake-up’ strokes. Table 62.3 [2], [11] There are specific inclusion and exclusion criteria, as per stroke unit guidelines.

Table 62.3



Eligibility criteria for extending thrombolysis to 4.5–9 hours and wake-up stroke[2]

	TIME WINDOW	IMAGING	IMAGING CRITERIA
Wake-up stroke	>4.5 hours from last seen well, no upper limit	MRI DWI-FLAIR mismatch	DWI lesion and no FLAIR lesion
Wake-up stroke or unknown onset time	>4.5 hours from last seen well, and within 9 hours of the midpoint of sleep. The midpoint of sleep is the time halfway between going to bed and waking up	CT or MRI core-perfusion mismatch	Suggested: mismatch ratio greater than 1.2, a mismatch volume greater than 10 mL, and an ischaemic core volume <70 mL
Known onset time	4.5–9 hours	CT or MRI core-perfusion mismatch	Suggested: mismatch ratio greater than 1.2, a mismatch volume greater than 10 mL, and an ischaemic core volume <70 mL

Patients must be in an environment where they can be monitored for potential complications, the most serious of which is ICH. This risk is reduced where there is strict adherence to the inclusion and exclusion criteria and the appropriate dose used.

Endovascular Therapy

Several studies have shown positive results with mechanical thrombectomy in immediate and 90-day functional outcomes, specifically for patients with a large artery, anterior circulation and proximal occlusion in addition to thrombolysis and for patients who have contraindications to thrombolysis but not mechanical thrombectomy.[2,11–13] This procedure is available only in specialist neuroradiology departments, which have the support of a neurosurgical centre. Mechanical thrombectomy should be considered in anterior circulation strokes in the presence of (1) a large vessel occlusion (internal carotid artery, M1 or M2 branch occlusion), (2) within 12 hour of LSW (or wake-up stroke), and (3) a baseline modified Rankin scale score of 0–1 and (4) National Institutes of Health Stroke Scale (NIHSS) score >5. If LSW is 12–24 hours, advanced imaging is recommended. Discussion with an endovascular capable centre is advised even in patients with a less favourable ASPECT score.[14]

In posterior circulation strokes, the BAOCHE multicentred randomised trial has been published informing current guidance that advise referral for mechanical thrombectomy if LSW within 12–24 hours.[2] Of note, while there is a small group of patients who have contraindications to tPA, mechanical thrombectomy may be considered. Current guidance is still that tPA is still the standard of care whether mechanical thrombectomy is being considered or not.

Decompressive Craniectomy

Some patients with malignant middle cerebral artery infarction syndrome (MMCAS) (Fig. 62.1) may benefit from decompressive craniectomy, especially patients with large middle cerebral artery territory infarcts aged <60 years. Decompressive craniectomy must be referred to the neurosurgical centre within 24 hours and the procedure completed within 48 hours of symptom onset.[2]

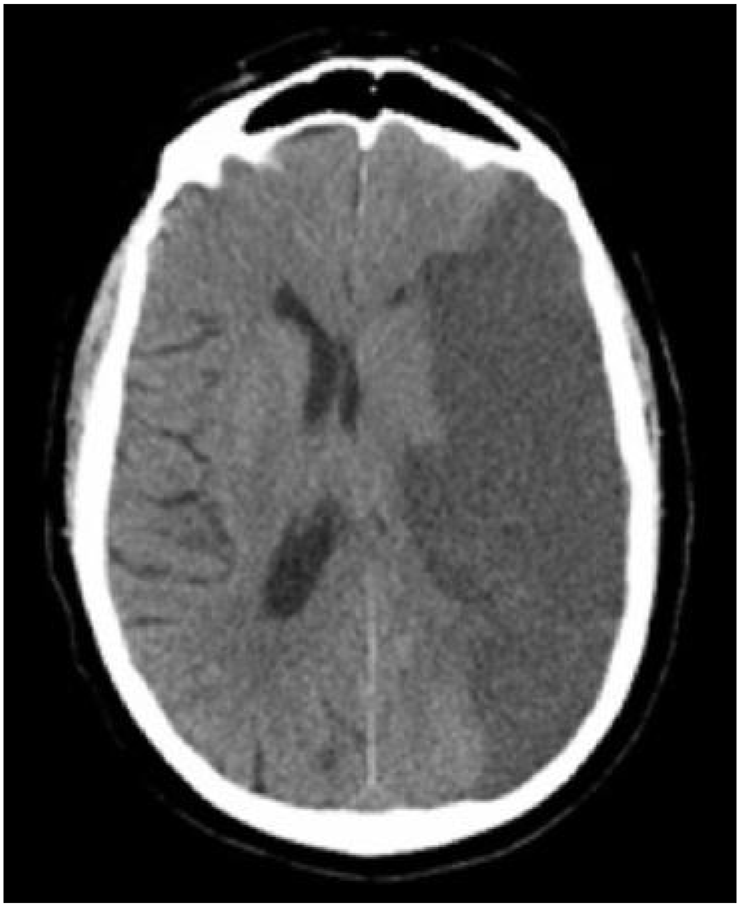


FIG. 62.1 Malignant MCA infarct.

Untreated, MMCAS has a mortality of 80%; craniectomy can reduce mortality to around 30% but with residual neurological deficit. Craniectomy has to be large enough to extend past the margins of the infarct. This seems to be well tolerated even after thrombolysis. There is no difference in outcome whether dominant or non-dominant hemispheres are involved. Patients who survive after craniectomy have moderate to severe disability and may have a high incidence of psychological complications. Studies have shown the benefit of this procedure for patients over 60 years. [15] In the over 60s, the outcome benefit for delayed decompressive craniectomy (after 48 hours) is still uncertain. [16]

Other forms of surgical intervention proven to be effective in making more intracranial space and reducing ICP are drainage of secondary hydrocephalus by extraventricular drain (EVD) insertion or evacuation of haemorrhage into infarcted areas, resulting in new compressive symptoms.

This is especially useful in the posterior fossa where the room for expansion of mass lesions is limited by its anatomy.

Complications of Stroke

These are summarised in Table 62.4

Table 62.4

Complications of stroke

COMPLICATION	COMMENT
Local complications:	
Cerebral oedema	
Haemorrhagic transformation	
Hydrocephalus	
General complications:	
Dysphagia	Increased risk of aspiration pneumonia
Fever	Associated with worse outcome in stroke patients
Infections	UTI, pneumonia
Acute myocardial infarction	1%–2% in stroke patients
Cardiac arrythmias	Including AF (which is a risk factor for stroke)
Acute kidney injury	10% of stroke patients
Gastro-intestinal bleed	1.1%–3%; can be reduced by using an H2-blocker or PPI
Seizures	To exclude if GCS not in keeping with area of stroke
Pressure ulcers	Nutritional and protein requirements are important in reducing the risk
Deep-vein thrombosis	Prevention is mostly based on mechanical devices

COMPLICATION	COMMENT
Contractures	Physiotherapy and regular passive movement are important
Depression	Can be difficult to treat
Post stroke fatigue	

A multidisciplinary team approach of doctors, pharmacists, specialist nursing, physiotherapists, phycologists, occupational and speech and language therapists is best able to avoid these complications. [23]

Spontaneous Intracranial Haemorrhage

Spontaneous ICH resulting in stroke may occur from either intracerebral haemorrhage (10%) or SAH (5%)- 85% of strokes will be ischaemic strokes.

Intracerebral Haemorrhage

The incidence of intracerebral haemorrhage is about 9/100,000 of the population, occurring mostly in the age range of 40–70 years, with an equal incidence in males and females.

Aetiology and Pathology

The commonest cause is the effect of chronic systemic hypertension. It may also occur in malignant tumour neovasculature, vasculitis, mycotic aneurysms, amyloidosis, sarcoidosis, malignant hypertension, primary haemorrhagic disorders and over-anticoagulation. Up to 14% of patients who developed COVID-19 from SARS-CoV2 infection also developed haemorrhagic stroke, more in patients who needed ECMO. [3]

Occasionally, cerebral aneurysms or AVMs may cause intracerebral haemorrhage without SAH. Where intracerebral haemorrhage occurs in young patients, the most likely cause is an underlying vascular abnormality.

This is also associated with the abuse of drugs with sympathomimetic activity, such as cocaine. Common sites of haemorrhage are the putamen (55%), cerebral cortex (15%), thalamus (10%), pons (10%) and cerebellum (10%). The effect of the haemorrhage is determined by the area of brain tissue that it affects. Cortical haemorrhages tend to be larger than pontine bleeds (Fig. 62.2), but the latter is much more destructive owing to the anatomical density of neural tracts and nuclei.

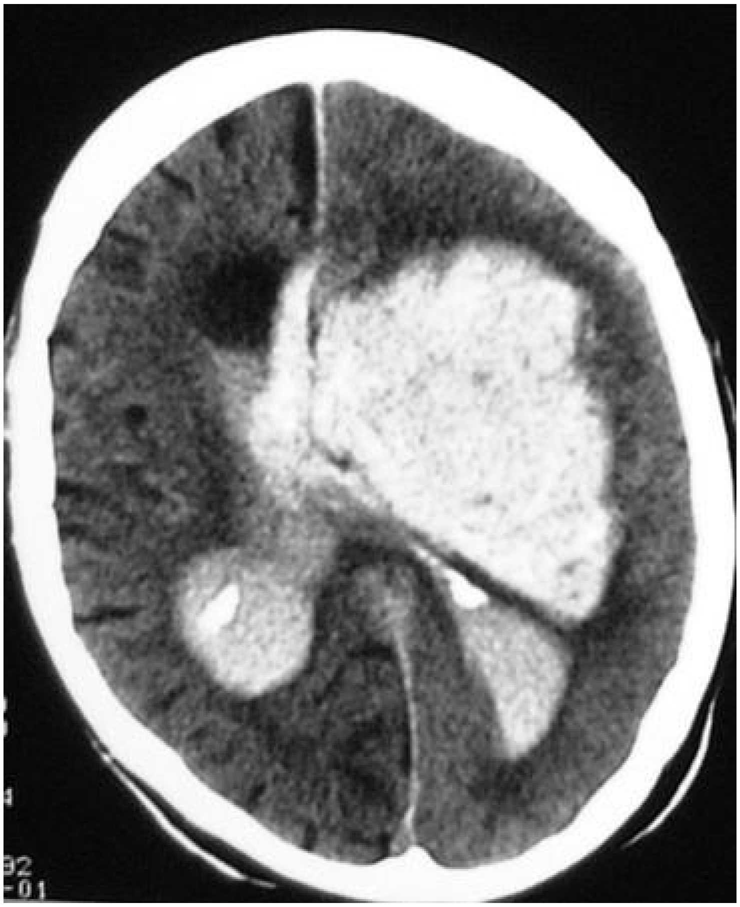

FIG. 62.2 Devastating intracerebral haemorrhage.

Clinical Presentation

Usually, there are no prodromal symptoms, and a sudden onset of focal neurology or depressed level of consciousness occurs. Headache and neck stiffness will occur in conscious patients if there is subarachnoid extension by haemorrhage into the ventricles. Where intraventricular extension occurs, there may be a progressive fall in GCS as secondary hydrocephalus occurs, and this may be accompanied by ocular palsies, resulting in ‘sunset eyes’. Early deterioration is common in the first few hours after haemorrhagic stroke and more than 20% of patients will drop their GCS score by two or more points between the initial onset of symptoms and arrival in the emergency department.[17] As with ischaemic stroke, focal neurology is determined by which area of the brain is involved. The only way to differentiate absolutely between ischaemic, intracerebral and SAH is by appropriate imaging. The symptoms relate to tissue destruction, compression and raised ICP, which, if progressive, will result in brainstem ischaemia and death.

Investigations

The general investigations are essentially those listed previously for ischaemic stroke, since it is difficult to distinguish between the two in the early stages. Patients undergoing treatment with oral anticoagulants, particularly warfarin or direct oral anticoagulants (DOAC) in atrial fibrillation, mean that anticoagulant-associated ICH is increasing in frequency and a full coagulation screen is essential.[17,18] CT scan and/or MRI of the brain should be performed at the earliest opportunity. The early deterioration seen in ICH relates to active bleeding and repeat imaging after 3 hours of symptom onset often shows significant enlargement of the initial haematoma. CTA/MRA or venography is very important to determine the cause of the haemorrhage such as AVM, aneurysm, cerebral venous thrombosis or tumour neovasculature. In patients with COVID-19 neurological observations are essential, especially while mechanically ventilated.

Management

The general management principles are identical to those for ischaemic stroke. There is, of course, no place for anticoagulation or thrombolysis, and reversal of any coagulation defect, either primary or secondary to therapeutic anticoagulation, must be undertaken as a matter of urgency. A full coagulation screen must be performed and the administration of vitamin K, fresh frozen plasma, cryoprecipitate, prothrombin complex concentrate or specific DOAC antidote should be directed by haematology advice and drug availability. Where emergency decompressive surgery is indicated, warfarin or DOAC-induced coagulopathy should be corrected using prothrombin complex concentrate. Intraventricular extension occurs in around 45% of cases and the insertion of an EVD may increase the conscious level, particularly in the presence of secondary hydrocephalus. The normal production of cerebral spinal fluid (CSF) should produce an hourly output and a sudden fall in output to zero should alert to the possibility that the drain has been blocked. If the drain is blocked, secondary hydrocephalus will recur. Because of the risk of introducing infection and causing ventriculitis, the drain must be unblocked in a sterile manner by a neurosurgeon. Blood in the CSF acts as a pyrogen, but pyrexia should never be ascribed to this alone, and regular blood cultures and CSF samples are required as part of sepsis surveillance; procalcitonin may help guide the need for antibiotics. Operative decompression of the haematoma should be undertaken only in neurosurgical centres, and safe transfer must be assured if this is being considered. The administration of hyperosmolar therapy prior to transfer should be discussed with the neurosurgical unit. Current recommendations of the American Heart Association/American Stroke Association (AHA/ASA) are: ‘For patients with cerebellar haemorrhage, indications for immediate surgical evacuation with or without an external ventricular drain to reduce mortality now include larger volume (>15 mL) in addition to previously recommended indications of neurological deterioration, brainstem compression, and hydrocephalus’. [17] The management of hypertension following spontaneous intracerebral haemorrhage may be difficult as too high a BP may provoke further bleeding, whereas too low a BP may result in cerebral ischaemia. Initial systolic BP should be >110 mm Hg and <140 mmHg. If there are any surgical interventions, outcomes are worse if systolic BP is <100 mm Hg. After initial assessment and post-procedure, systolic BP should be maintained at 130–140 mm Hg for 7 days. [2, 19] There is no place for steroids, continuous hyperosmolar therapy (to maintain higher sodium or reduce cerebral oedema) or prophylactic antiepileptic drugs in the management of ICH. The use of platelet infusions unless platelets are very low is associated with a worse outcome.[17] Hyperventilation to a $PaCO_2$ of 30 mm Hg (4 kPa) or less to control raised ICP can have detrimental effects on cerebral blood flow in other areas of the brain. Discussion with relatives when patients have no capacity, around what the person values and long-term outcomes, are important.

Subarachnoid Haemorrhage

SAH refers to bleeding that occurs principally in the subarachnoid space and not into the brain parenchyma. The incidence of SAH is around 6/100,000; the apparent decrease in incidence, compared with earlier studies, is due to the more frequent use of CT scanning, which allows the exclusion of other types of haemorrhage. Risk factors are the same as for stroke, but SAH patients are usually younger, peaking in the sixth decade, with a female-to-male ratio of 1.3:1. The only modifiable risk factors for SAH are smoking, the use of sympathomimetics (e.g. cocaine) and hypertension, which increase the risk odds ratio by 2 to 3. Family history is important as people with ≥2 first-degree relatives with aneurysmal subarachnoid bleeds have a 12% chance of having an aneurysm.[20] Overall mortality is 30%, of which 18%–24% die before reaching the hospital, with up to 10% of survivors having residual deficit-producing dependency.[20]

Aetiology and Pathology

The majority of cases of SAH are caused by ruptured saccular (berry) aneurysms (85%), the remainder being caused by non-aneurysmal perimesencephalic haemorrhage (10%) and rarer causes, such as arterial dissection, cerebral or dural AVMs, mycotic aneurysm, pituitary apoplexy, vascular lesions at the top of the spinal cord and cocaine abuse. Sudden hypertension plays a role in causing rupture, as shown by SAH in pericoital SAH, patients taking crack cocaine or, rarely, high doses of decongestants, such as pseudoephedrine.

Clinical Presentation

Classically, there is a ‘thunderclap’ headache developing in seconds, with half of the patients describing its onset as instantaneous. This is followed by a period of depressed consciousness for less than 1 hour in 50% of patients, with focal neurology in about 30% of patients. About one-fifth of patients recall similar headaches and these may have been due to sentinel bleeds; this increases the chances of early rebleed 10-fold. The degree of depression of consciousness depends upon the site and extent of the haemorrhage. Meningism, neck stiffness, photophobia, vomiting and a positive Kernig’s sign, are common in those patients with higher GCS. A high index of suspicion is needed for patients presenting with the classical headache; a non-contrast CT scan is recommended; the sensitivity of the CT scan is most within 6 hours after ictus [21] and, if negative, a lumbar puncture should be performed 12 hours after ictus. If that is also negative, consider CTA.

The clinical severity of SAH is often described by a grade, the most widely used being that described by the World Federation of Neurological Surgeons (WFNS), which is summarised in Table 62.5 . This grading, together with the extent of the haemorrhage and the age of the patient, gives some indication of the prognosis, in that the worse the grade the bigger the bleed, and the older the patient the less likely is a good prognosis. Scales that combine radiological and clinical signs have helped with prognostication and severity assessment, such as VASOGRADE [22] Other poor prognostic signs are pre-existing severe medical illness, clinically symptomatic vasospasm, delayed multiple cerebral infarctions, hyperglycaemia, fever, anaemia and medical complications, such as pneumonia and sepsis. Anatomical risk factors may increase the periprocedural risk of complications. On the other hand, better outcomes seem to be associated with treatment in a high-volume neurosurgical centre.

Table 62.5

GCS, Glasgow Coma Score; *WFNS,* World Federation of Neurological Surgeons.

Complications

The clinical status of the patient may be complicated by factors other than the physical effect of the initial bleed. Factors, such as acute hydrocephalus, early rebleeding, cerebral vasospasm, parenchymal haematoma, seizures and medical complications, must be considered.

Rebleeding

This may occur within the first few hours after admission and 15% of patients may deteriorate from their admission status. The chance of rebleeding is dependent on the site of the aneurysm, the presence of the clot, the degree of vasospasm and the age and sex of the patient. Although most studies quote an incidence for rebleeding of 4% in the first 24 hours, more recent studies suggest an incidence of 9%–17% with most cases occurring within 6 hours. Anticoagulation should be reversed. BP control is important and avoidance of hypotension and hypertension should be the aim. Systolic BP of 120–160 mm Hg in the unsecured aneurysm patient. [19] The use of antifibrinolytics has not improved outcome and as such is not routinely recommended. [24] The best way to prevent rebleeding is by securing the aneurysm as soon as possible, which can be by clipping or coiling. [20]

Acute Hydrocephalus

This may occur within the first 24 hours post ictus and is often characterised by a drop in the GCS score, sluggish pupillary responses and bilateral downward deviation of the eyes (‘sunset eyes’). If these signs occur, a CT scan should be repeated and, if hydrocephalus is confirmed or there is a large amount of intraventricular blood, then an EVD may be inserted. There is conflicting evidence on EVD insertion before securing the aneurysm causing rebleeding. [20]

Delayed Cerebral Ischaemia

Vasospasm is the term used to describe the narrowing of the cerebral blood vessels in response to the SAH seen on angiography. It occurs in up to 70% of patients, but not all of these patients will have symptoms. As such the use of calcium channel blockers, most frequently nimodipine, for the prevention of delayed cerebral ischaemia (DCI) is recommended for 21 days. DCI refers to the onset of focal neurological deficit, a drop in GCS by 2 or more points, and/or cerebral infarction that occurs typically 4–12 days post-SAH unrelated to aneurysm treatment or other causes of neurological deficit, such as hydrocephalus, cerebral oedema or metabolic disorder. [20] The use of transcranial Doppler (TCD) to estimate middle cerebral artery blood velocity has shown that a velocity of more than 120 cm/s correlates with angiographic evidence of vasospasm. This technology allows diagnosis in the ICU and provides a means of monitoring the success of treatment to reduce DCI, which is undertaken to reduce the severity of delayed neurological deficits secondary to vasospasm. The problem is that not all patients who have angiographic vasospasm or high Doppler velocities have symptoms. If there is evidence of a depressed level of consciousness in the absence of rebleeding, hydrocephalus or metabolic disturbances, but there is evidence of DCI clinically, on TCD or angiogram, then it would seem appropriate to initiate treatment. If vasospasm occurs at the time of angiography or coiling, then intravascular vasodilators, such as papaverine or nimodipine have been used. CTA is the imaging modality of choice unless intracerebral therapy is planned, then digital subtraction angiography (DSA) is recommended as first-line imaging. Once the aneurysm has been secured the BP can be augmented above pre-secured targets, while maintaining euvolaemia. This may improve neurological signs. [20]

Parenchymal Haematoma

This may occur in up to 30% of SAHs following aneurysm rupture and has a much worse prognosis than SAH alone. If there is a mass effect with compressive symptoms then evacuation of haematoma is recommended, to improve outcome. [20]

Medical Complications

Medical complications will occur in 40% of SAH patients. The mortality due to medical complications is almost the same as that due to the combined effects of the initial bleed, rebleeds and DCI. The types of medical complications seen are shown in Table 62.6 .

Table 62.6

Types of medical complication and treatment in patients with subarachnoid haemorrhage

MEDICAL COMPLICATION	INCIDENCE (%)	TREATMENT
Arrhythmias	35	Arrhythmias require correction of trigger factors, such as hypovolaemia and electrolyte or acid-base disturbances prior to the appropriate antiarrhythmic drug or direct current cardioversion. Cardiac function should be evaluated in patients with cardiovascular deterioration, by means of serial enzymes and echocardiography. Cardiac output monitoring should be considered
Liver dysfunction	24	Review the use of drugs that can cause liver dysfunction
Neurogenic pulmonary oedema	23	Neurogenic pulmonary oedema may be associated with severe cardiogenic shock. The cardiogenic shock is reversible and patients can make a good recovery despite the need for aggressive support [20]
Pneumonia	22	Pneumonia may require continuous positive airway pressure or ventilatory support

MEDICAL COMPLICATION	**INCIDENCE (%)**	**TREATMENT**
		together with directed antimicrobial therapy
ARDS and atelectasis	20	Acute respiratory distress syndrome requires lung-protective/recruitment ventilatory strategies or proning
Renal dysfunction	5	Renal failure necessitates an appropriate means of renal replacement therapy
Dysnatraemia	30%	Hyponatraemia is implicated in DCI. The aim is for euvolaemia; if it cannot be achieved because of a persistent negative fluid balance as a result of CSWS, then fludrocortisone/corticosteroids should be considered. Hyponatraemia should be corrected by no more than 0.5 mmol/L per hour with a maximum of 8 mmol/L per day (if it is chronic; i.e. of more than 48 hours' duration) during which 4-hourly sodium levels should be taken. This may be achieved by using intravenous fluid that has more sodium than the serum concentration of the patient. In patients who are resistant to

MEDICAL COMPLICATION	**INCIDENCE (%)**	**TREATMENT**
		vasopressors, hypothalamic dysfunction should be considered and hydrocortisone should be administered, but no more than 300 mg/day [7]
Hypo/hyperglycaemia		Blood glucose should be kept at 4.4–11.1 mmol/L (80–200 mg/dL), as higher and lower levels of blood glucose have been shown to be detrimental to the outcome
Fever		Fever should be controlled by antipyretics as the first-line treatment, especially when DCI is suspected. Cooling devices should be considered if first-line antipyretics have failed, but care should be taken to monitor for pressure ulcers and venous thrombotic events. Shivering needs to be addressed as this will be counterproductive to therapy by increasing oxygen consumption
Deep-vein thrombosis		Deep-vein thrombosis prophylaxis should be instituted as soon as possible in the form of graduated compression devices; heparin (unfractionated or low molecular weight) should be

MEDICAL COMPLICATION	INCIDENCE (%)	TREATMENT
		started 24 hours after securing the aneurysm [20]
Anaemia		Anaemia should be minimised by limiting the amount of blood taken for blood tests. A transfusion trigger of 80 g/L in patients without DCI and 90–100 g/L in patients with DCI has been recommended [22]

ARDS, Acute respiratory distress syndrome.

Investigations

The general investigations for stroke should be performed, and early CT imaging is mandatory. Blood appears characteristically hyperdense on CT and the pattern of haemorrhage may enable localisation of the arterial territory involved (Fig. 62.3). Very rarely, a false-positive diagnosis may be made if there is severe generalised oedema resulting in venous congestion in the subarachnoid space. Small amounts of blood may not be detected, and the incidence of false-negative reports is around 2%. [20] It may be difficult to distinguish between post-traumatic SAH and primary aneurysmal SAH, which precipitates a fall in the level of consciousness that provokes an accident or fall. MR scanning is particularly effective for localising the bleed after 48 hours when extravasated blood is denatured, and provides a good signal on MRI.

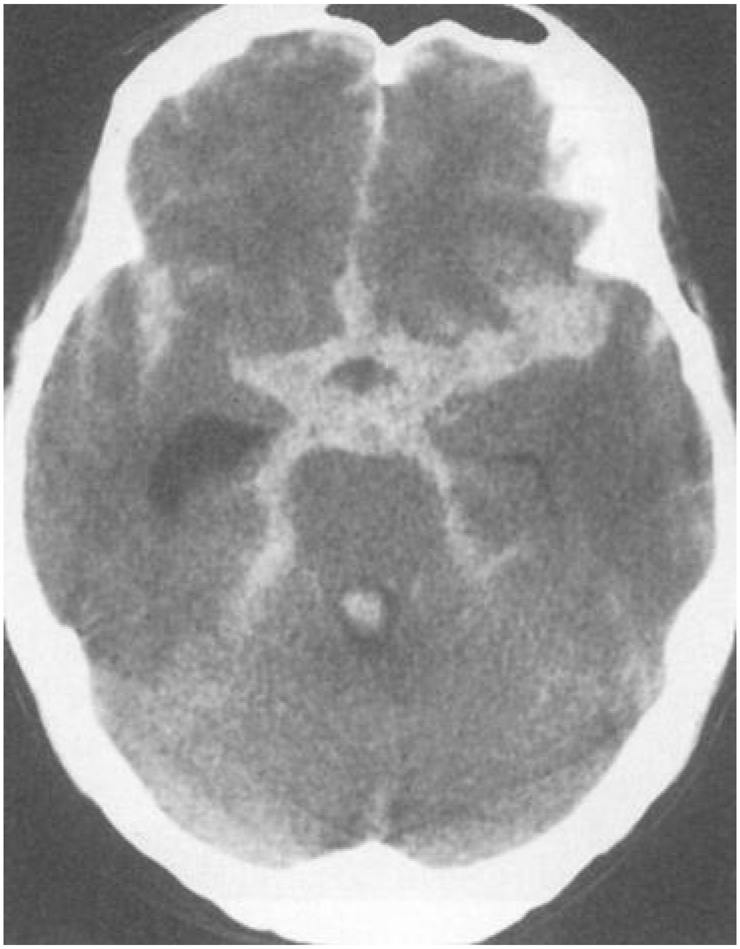

FIG. 62.3 Subarachnoid haemorrhage on computed tomography scan of the head.

Lumbar puncture is still necessary in those patients where the suspicion of SAH is high despite a negative CT, or there is a need to exclude infection. There must be no raised ICP and at least 12 hours should have passed to give time for the blood in the CSF to lyse, enabling xanthochromia to develop.

Digital subtraction angiography (DSA) via arterial catheterisation is still the most commonly used investigation for localising the aneurysm or other vascular abnormality prior to surgery. It is not without risk and aneurysms may rupture during the procedure; a meta-analysis has shown a complication rate of 1.8%. Other methods under investigation include CTA and MRA. DSA is the diagnostic tool of choice in cases where CTA is still inconclusive. [20]

ICP monitoring is of limited use in SAH patients except in those where hydrocephalus or parenchymal haematoma is present, and early detection of pressure increases may be the trigger for drainage or decompressive surgery. [20]

Multimodal monitoring: TCD studies may be useful in detecting vasospasm or those patients in whom autoregulation is impaired. [21] The technique is dependent on there being a ‘window’ of thin temporal bone allowing insonation of the Doppler signal along the middle cerebral artery. It is very user dependent and 15% of patients do not have an adequate bone window. Continuous electroencephalogram (EEG) monitoring, cerebral blood flow monitoring, brain tissue oxygen oximetry and cerebral microdialysis have all been used to diagnose DCI. [21]

Management

The initial management of SAH is influenced by the grading, medical co-morbidity or complications, and the timing or need for surgery. Patients with decreased GCS may need early intubation and ventilation, simply for airway protection, whereas those with less severe symptoms require regular neurological observation, analgesia for headache and bed rest prior to investigation and surgery. Other management considerations are stress ulcer prophylaxis, deep-vein thrombosis prophylaxis using compression stockings or boots, and seizure control with phenytoin or barbiturates. If the patient is sedated and mechanically ventilated, the use of modified EEG/EEG should be considered to detect subclinical seizure activity.

Hyponatraemia is a common finding and adequate fluid therapy with normal saline is required with electrolyte levels maintained in the normal range. Occasionally, as in other types of brain injury, excessive natriuresis occurs and may result in hyponatraemic dehydration and cerebral salt-wasting syndrome (CSWS). [20] Its aetiology is not known, but some suggest increased levels of atrial natriuretic peptide. It usually occurs within the first week after insult and resolves spontaneously in 2–4 weeks. Failure to distinguish CSWS from the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) could lead to inappropriate treatment by fluid restriction, which would have adverse effects on cerebral perfusion.

Urine sodium concentrations are usually elevated in both SIADH and CSWS (>40 mmol/L) but urinary sodium excretion, urine sodium concentration [Na mmol/L] × urine volume [L/24 hours] is high in CSWS and normal in SIADH. If CSWS does not respond to fluid replacement with saline or is not self-limiting then fludrocortisone or corticosteroid therapy may be useful. Euvolaemia is crucial to help prevent and not exacerbate DCI. [20]

Blood Pressure Control

Elevation of BP is commonly seen after SAH. International guidelines recommend that systolic BP is kept <160 mm Hg or mean arterial pressure of <110 mm Hg in a person with an unsecured aneurysmal SAH, with some evidence showing an SAP of 140–160 mm Hg is recommended. [20] Beta-adrenergic blockers or calcium antagonists are the most widely used agents, since drugs producing cerebral vasodilation may increase intra cranial pressure (ICP). The choice is less important than the titratability of the drug, as the balance between the increased risk of rebleed and cerebral perfusion needs to be maintained. If nimodipine causes severe hypotension, timing and dose can be changed (i.e. 30 mg 2-hourly instead of 60 mg 4-hourly). If nimodipine still remains a problem, consider omitting doses until the patient is more cardiovascularly stable while maintaining euvolaemia.

Delayed Cerebral Ischaemia

Angiographic demonstration of vasospasm may be seen in about 70% of SAH patients, but only about 30% develop cerebral symptoms related to vasospasm, hence the change of nomenclature. Symptoms tend to occur between 4- and 14-days post-bleed, which is the period when cerebral blood flow is decreased after SAH.

Prevention

One method of pre-empting vasospasm is oral nimodipine at 60 mg given 4-hourly for 21 days, which has been shown to achieve a reduction in the risk of ischaemic stroke by 34%. Intravenous nimodipine should be used in patients who are not absorbing enterally, but it must be titrated against BP to avoid hypotension. Aspirin, clazosentan, enoxaparin, erythropoietin, fludrocortisone, magnesium, methylprednisolone, nicardipine and statins have been in trials but have not been shown to prevent DCI. [20]

Treatment

Low cerebral blood flow is known to worsen outcomes and this resulted in the development of prophylactic hypertensive hypervolaemic haemodilution, so-called ‘triple-H therapy’. This has been shown to cause harm. The focus now is on euvolaemia and, if indicated, hypertension can be induced with vasopressors. This needs to be done in a stepwise fashion with the assessment of neurological function at each step. [20] Cerebral angioplasty or direct intracerebral vasodilators should be considered if induced hypertension is not reversing the DCI symptoms. Where symptoms develop it is important to exclude other causes, such as rebleeding, hydrocephalus or metabolic disorder. Poor-grade SAH patients who are sedated or have low GCS are clinically difficult to assess; multimodal monitoring is recommended to look for deterioration. [20]

Seizures

Seizure occurs in up to 26% of SAH patients, however, the evidence for prophylactic use of anticonvulsants is poor and not recommended. Treatment with antiepileptics for a patient who has had a seizure is recommended for 7 days. [20] Some prognostic indicators for the development of seizures have been identified: increased intracerebral blood, poor-grade SAH, rebleeding infarction and middle cerebral artery (MCA) aneurysm. Patients should be observed for seizure activity and treated appropriately. A patient with poor-grade SAH who is not improving or is deteriorating neurologically, from an unknown cause, should have continuous EEG monitoring to rule out seizure activity. [20]

Surgery

Clipping of the aneurysm is the surgical treatment of choice, with wrapping, proximal ligation or bypass grafting being used if the aneurysm is inaccessible to Yasargil clipping. Recommendations are to secure the aneurysm as soon as possible after ictus or presentation. Large intracerebral haematomas associated with the SAH and middle cerebral artery aneurysms should be strongly considered for surgery. There is no good level-one evidence for the use of induced hypertension or hypothermia during clipping, but in certain patients, it could be considered. What is clear is that hypotension and hyperglycaemia should be avoided. [20]

Endovascular Coiling

In patients with ruptured intracranial aneurysms suitable for both surgery and endovascular coiling treatments, endovascular coiling is more likely to result in independent survival at 1 year than neurosurgical clipping; the survival benefit continues for at least 7 years. The risk of late rebleeding is low but is more common after endovascular coiling than after neurosurgical clipping as well as retreatment of up to 20%. [20] Additional complications of coiling include rupture during catheter placement in the aneurysm, coil embolisation and vasospasm. Not all aneurysms, particularly those with wide necks, multiple filling vessels or giant aneurysms, are suitable for coiling. Aneurysms that are amenable to either surgery or coiling should be coiled; if patients are elderly (>70 years) or have poor-grade SAH then coiling is preferred. Patients with an SAH from ruptured blister/fusiform aneurysm or wide-neck aneurysms not amenable to surgical clipping or primary coiling, endo-vascular treatment with stent-assisted coiling or flow diverters is reasonable to reduce the risk of rebleed. [20]

Therapy of Medical Complications

This is summarised in Table 62.6

Rehabilitation

Early multidisciplinary discussions help with family engagement and planning of rehabilitation needs. There needs to be discussions with the patient if able, or relatives around what constitutes an acceptable outcome for the patient. This should be taken into consideration around planning care needs and the burden of interventions.

Future Directions

Artificial intelligence is being used to screen CT scans for ICH, SAH and strokes in certain centres. This makes diagnosis faster and more sensitive. New surgical and interventional radiological techniques are being researched to secure aneurysms. There are a few areas of research targeting spreading depolarisations, these are slow-spreading waves that signify metabolic collapse. Often not seen on scalp EEG, but on subdural or intracortical EEG. This can also pick up localised seizures and other seizure patterns known as the ictal-interictal continuum (identification of this is a developing area). [25]

Meningitis and encephalomyelitis

Michel Toledano and Nicholas WS Davies

Introduction

Infections of the cranial contents can be divided into those affecting the meninges (meningitis; empyema) and those affecting the brain parenchyma (encephalitis; abscess). Involvement of the spinal cord is termed myelitis. Chronic, insidious or rare infections are beyond the scope of this chapter, which will focus on acute bacterial and viral causes of meningitis, encephalomyelitis and abscess/empyema in adults.

The crucial diagnostic questions to be considered for an individual patient with a neurological infection are to determine why this individual, in this place, has developed this disease at this time. [1]

All patients presenting with symptoms or signs suggestive of meningitis or encephalitis warrant immediate testing for human immunodeficiency virus (HIV) infection.

Definitions

- *Meningitis:* is inflammation of the meninges and subarachnoid space, which may be caused by infection. Infection can be caused by viruses, bacteria, fungi or protozoa. Meningeal inflammation may also be caused by subarachnoid haemorrhage, vaccination or be a manifestation of other multiorgan diseases such as systemic lupus erythematosus, sarcoidosis, lymphoma or meningeal micrometastases from a disseminated carcinoma.

- *Aseptic meningitis:* is a generic term for cases of meningitis in which bacteria cannot be isolated from the cerebrospinal fluid (CSF). The differential diagnosis includes: (1) viral meningitis, (2) partially treated bacterial meningitis, (3) tuberculosis (TB) meningitis, (4) fungal meningitis, (5) lymphoma, (6) sarcoidosis, (7) drug-induced meningitis and (8) other collagen vascular diseases. The most common causes of aseptic meningitis are viral infections.
- *Encephalitis:* is inflammation of the brain parenchyma, which can be due to infection or immune-mediated processes. Patients may have a history of focal symptoms including preceding seizures together with cognitive or behavioural symptoms.
- *Tuberculous meningitis:* causes subacute lymphocytic meningitis. Patients may have a non-specific prodromal phase, including symptoms such as headache, vomiting and fever.
- *Subdural empyema:* a suppurative process in the space between the pia and dura maters.
- *Brain abscess:* a collection of pus within the brain tissue.

Bacterial Meningitis

Bacterial meningitis is an inflammatory response to infection of the leptomeninges and subarachnoid space. This is characterised by the clinical syndrome of fever, headache, neck stiffness and CSF pleocytosis. Despite antibiotic therapy, some patients continue to suffer significant morbidity and mortality.

Bacterial organisms are usually not confined to the brain and meninges and frequently cause systemic illness, for example severe sepsis, shock, acute respiratory distress syndrome and bleeding disorders such as disseminated intravascular coagulation (DIC).[2,3]

A variety of other pathogens cause meningeal inflammation, resulting in very similar clinical presentations. Bacterial infections must be treated urgently and appropriately to limit ongoing central nervous system (CNS) damage. It is also important to treat the complications of meningitis such as seizures and raised intracranial pressure (ICP).

Where possible, spinal fluid examination following a lumbar puncture is required to confirm the diagnosis and establish the pathogenic organism responsible.[4] A CSF examination may be contraindicated if there are signs of raised ICP including:

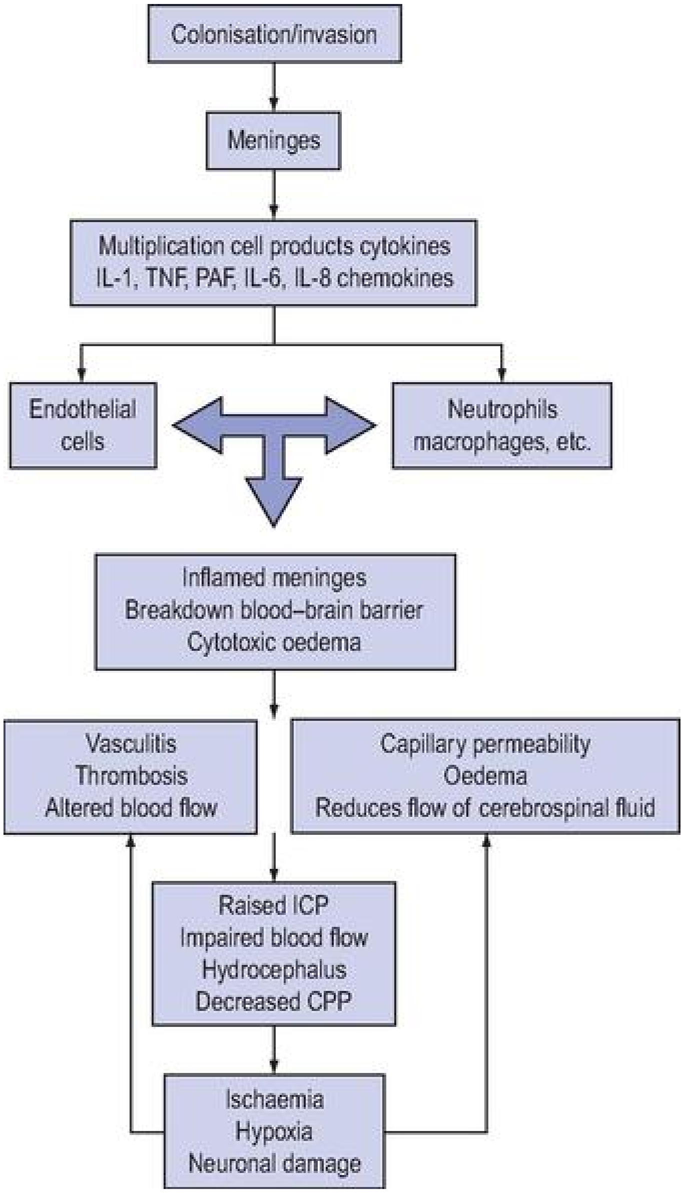
- papilloedema
- focal neurological signs
- seizures
- Glasgow Coma Scale (GCS) ≤12

These features raise the possibility of an undiagnosed cerebral mass lesion or malignant cerebral oedema, which could cause cerebral herniation should a lumbar puncture be performed. A computed tomography (CT) brain scan is required prior to CSF examination to rule out this possibility and lessen, but not obviate, the risk of cerebral herniation. Even if the CT brain scan is normal, ICP may be raised. The importance of performing a safe CSF examination must be balanced against the need to commence immediate treatment for each individual patient.[4–6]

Pathogenesis

All three main causes of bacterial meningitis (see later) are spread by droplet infection or exchange of saliva. Bacterial meningitis may occur when pathogenic organisms colonise the nasopharynx and reach the blood–brain barrier. It can also occur as a consequence of infection in the middle ear, sinus or teeth leading to secondary meningeal infection. Most bacteria obtain entry into the CNS via the haematogenous route. As the organisms multiply, exponentially, they release cell wall products and lipopolysaccharides, which can generate a local inflammatory reaction that itself also releases inflammatory mediators. The net result of the release of cytokines, tumour necrosis factor and other factors is associated with a significant inflammatory response. Vasculitis of CNS vessels, thrombosis, cell damage and exudative material all contribute to vasogenic and cytotoxic oedema, altered blood flow and cerebral perfusion pressure. Later on, infarction and raised ICP occur.[4,7]

The inflammatory events seen with infection are summarised in Fig. 63.1.



Colonisation/invasion
Meninges
Multiplication cell products cytokines IL-1, TNF, PAF, IL-6, IL-8 chemokines
Endothelial cells
Neutrophils macrophages, etc.
Inflamed meninges
Breakdown blood–brain barrier
Cytotoxic oedema
Vasculitis
Thrombosis
Altered blood flow
Capillary permeability
Oedema
Reduces flow of cerebrospinal fluid
Raised ICP
Impaired blood flow
Hydrocephalus
Decreased CPP
Ischaemia
Hypoxia
Neuronal damage

The flowchart depicts a cascade of events in meninges involving colonisation/invasion leading to multiplication of cell products cytokines interleukin-1, tumour necrosis factor, platelet-activating factor, interleukin-6, interleukin-8 chemokines that affect either the endothelial cells or the neutrophils macrophages, and others causing inflamed meninges, breakdown blood–brain barrier, and cytotoxic oedema. These factors, along with raised intracranial pressure, impaired blood flow, hydrocephalus, or decreased cerebral perfusion pressure, lead to ischaemia, hypoxia, neuronal damage resulting in either vasculitis, thrombosis, altered blood flow or capillary permeability, oedema, or reduced flow of cerebrospinal fluid.

FIG. 63.1 Cascade of events in meningitis. *CPP* , Cerebral perfusion pressure; *ICP* , intracranial pressure; *IL* , interleukin; *PAF* , platelet-activating factor; *TNF* , tumour necrosis factor.

Aetiologies

Acute bacterial meningitis can be caused by many species of bacteria, although two organisms are commonly reported in resource-rich settings:

- *Streptococcus pneumoniae*
- *Neisseria meningitidis*

Until the advent of the meningitis vaccination programme, *Haemophilus influenzae* type B was the most common cause of bacterial meningitis. *S. pneumoniae* and *N. meningitidis* remain the most common causes of bacterial meningitis in adults worldwide. [4] *Listeria monocytogenes* can occur in the elderly, immunocompromised, or those with chronic illnesses such as alcohol dependency, diabetes, or malignancy. The emergence of pneumococcal strains resistant to penicillin has also influenced the epidemiology of meningitis. [8]

Nosocomial Infections

Common systemic nosocomial pathogens such as *Staphylococcus* species (spp.) *Escherichia coli* , *Pseudomonas* spp., *Klebsiella* and *Acinetobacter* spp. account for a high percentage of nosocomial infections of the meninges.

Immunocompromised Hosts

In the immunocompromised patient with meningitis (e.g. HIV or organ transplant patients), fungal (cryptococcal), viral (cytomegalovirus [CMV]) and mycobacterial meningitis should be considered. [9]

Neurosurgery and Trauma

Infections following skull trauma are frequently caused by *Staphylococcus aureus* and *Staphylococcus epidermis* , which should be considered in those with shunts or other intracranial devices.

Clinical Presentation

The history may reveal evidence of trauma or infection. Meningitis usually presents with an acute onset of:

- fever
- headache
- neck stiffness
- photophobia
- altered level of consciousness
- irritability

However, in the immunocompromised, elderly or infant patient, non-specific features such as a low-grade fever or mild behavioural change may be all that is apparent. Many of the classic symptoms are late manifestations of meningitis and are preceded by early symptoms such as leg pain or cold hands, which may not immediately suggest the more serious underlying diagnosis.

If the presenting symptoms are highly suggestive of pyogenic bacterial meningitis, empirical administration of a third-generation cephalosporin such as cefotaxime or ceftriaxone should be given.

It is important to identify from the history any reports of preceding trauma, upper respiratory tract infection or ear infection. Symptoms may develop over hours or days. Specific infections relate partly to an individual's age.

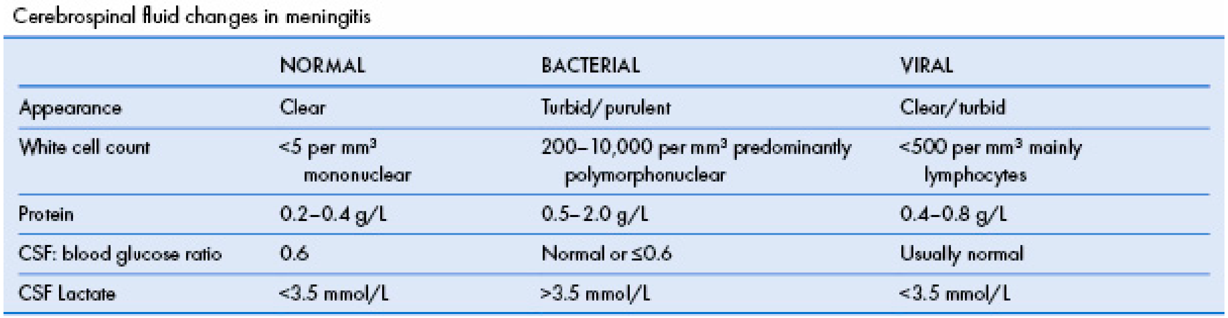
Neurological signs can be present with meningitis, but signs such as nuchal rigidity, stiffness and a positive Kernig's sign (pain and hamstring spasm resulting from attempts to straighten, e.g. with the hip flexed) are not always present; a number of studies have shown that the classic triad of signs was present in less than 50% of cases. Systemic signs occur most often in meningococcal disease where a haemorrhagic, petechial or purpuric rash may be observed. Digital gangrene or skin necrosis may occur. Some patients present severely septic with acute respiratory distress syndrome and DIC.

Approximately 25% of patients have a seizure during the course of the illness. There may be focal neurological signs in a minority of patients. Differential diagnoses include subarachnoid haemorrhage, migraine, encephalitis and tumour.

Investigations

The patient with suspected bacterial meningitis requires immediate blood cultures and collection of ethylenediaminetetraacetic acid (EDTA) blood samples for diagnostic polymerase chain reaction (PCR) studies.[4] Thereafter they should be given empirical intravenous (IV) antibiotics if there is likely to be any delay in further assessment (Table 63.1).

Table 63.1



Cerebrospinal fluid changes in meningitis

	NORMAL	BACTERIAL	VIRAL
Appearance	Clear	Turbid/purulent	Clear/turbid
White cell count	<5 per mm^3 mononuclear	200–10,000 per mm^3 predominantly polymorphonuclear	<500 per mm^3 mainly lymphocytes
Protein	0.2–0.4 g/L	0.5–2.0 g/L	0.4–0.8 g/L
CSF: blood glucose ratio	0.6	Normal or ≤ 0.6	Usually normal
CSF Lactate	<3.5 mmol/L	>3.5 mmol/L	<3.5 mmol/L

CSF , Cerebrospinal fluid.

Cerebrospinal Fluid Findings

A CSF examination is a vitally important investigation that will definitively confirm the diagnosis of bacterial meningitis. Its value should, in this regard, not be dismissed. Concern about the risks of coning following lumbar puncture should be considered in the context of patients' symptoms where the presence of coma, seizures, focal neurological signs and papilloedema may suggest raised ICP. Neuroimaging may not always predict whether it is safe to lumbar puncture a patient, although it may provide some level of reassurance that it is safe to proceed. A young patient who is alert, orientated, immune-competent and without focal signs can safely have a lumbar puncture without prior imaging.

Bacterial meningitis is suggested when there is:

- polymorphic leucocytosis
- low CSF glucose relative to the plasma value
- raised CSF protein concentration
- elevated CSF lactate (>3.5 mmol/L).

An urgent Gram stain and microbiological culture are mandatory. The Gram stain is positive in approximately 50%–60% of cases. A CSF examination shortly after empirical antibiotics may, but does not necessarily, decrease the diagnostic sensitivity of CSF culture. Bacterial latex agglutination tests applied to CSF have no greater sensitivity than Gram stain and may give non-specific results; care should be taken with their interpretation, and they should not be used alone to limit the spectrum of antimicrobial cover. PCR techniques can now be used to detect the presence of different organisms. A throat swab should be routinely taken. The clinical decision-making process to determine whether a patient does or does not have bacterial meningitis cannot be modelled easily and is reliant on both clinical and laboratory findings as well as patient observations over time.

As spread is haematogenous, blood cultures comprise an important investigation in meningitis, and a number of sets of cultures should be sent. It is advisable to routinely check a full blood count, clotting profile (to exclude DIC) and biochemistry including blood glucose level. A chest radiograph and blood gases should be performed to identify systemic involvement. Relevant areas such as infected sinuses or ears should be examined if there is any indication they are implicated.

Management

Broad-spectrum antibiotics should be started as early as possible and continued until bacterial identification is made (Table 63.2). Antibiotic selection is influenced by the clinical situation in conjunction with known allergies or local patterns of antibiotic resistance and the CSF findings. The patient’s travel history, exposure risks and level of immunocompetence are key to determining empirical antibiotic treatment. Delay in administering antibiotics is a significant risk factor for a poor prognosis. Adults with suspected meningitis should receive empirical treatment with ceftriaxone 2 g IV every 12 hours *or* 2 g cefotaxime IV every 6 hours (Table 63.3). [4]

Table 63.2

Empirical antibiotics for meningitis

INDICATION	ANTIBIOTIC	DOSE
<50 years	Ceftriaxone *or* cefotaxime	2 g IV 12-hourly, 2 g IV 6-hourly
>50 years or impaired cell immunity	Ceftriaxone *or* cefotaxime AND	2 g IV 12-hourly, 2 g IV 6-hourly
	Ampicillin *or* amoxicillin	2 g IV 4-hourly
Drug-resistant *Streptococcus pneumoniae* [a]	Ceftriaxone ANDVancomycin *or* Rifampicin	2 g IV 12-hourly15–20 IV mg/kg 12-hourly 600 mg IV or po 12-hourly
Neurosurgery shunt infection	Vancomycin ANDMeropenem	15–20 IV mg/kg 12-hourly2 g IV 6-hourly

[a] Add in IV vancomycin or rifampicin if penicillin resistance is suspected such as if the patient has travelled in the preceding 6 months to a country with a high prevalence of penicillin-resistant pneumococci.

IV , Intravenous.

Table 63.3

Alternative antibiotic choices for empirical treatment of meningitis

ORGANISM	ANTIBIOTIC	DOSE
<50 years	Chloramphenicol	25 mg/kg 6-hourly
>50 years or impaired cell immunity	Chloramphenicol AND	25 mg/kg 6-hourly
	Co-trimoxazole 10–20 mg/kg (of the trimethoprim component)	In four divided daily doses

Always check local sensitivity as resistance patterns are variable.

If the patient has within the last 6 months been to a country where resistant pneumococci are present, IV vancomycin 15–20 mg/kg should be added (*or* 600 mg rifampicin 12-hourly IV or orally). For travellers with meningitis, up-to-date information regarding antibiotic resistance should be sought from local microbiology services.

Those aged over 50? or immunocompromised (including diabetics and those with a history of alcohol misuse) should receive 2 g IV ampicillin *or* amoxicillin *in addition* to a cephalosporin.

It is more difficult to select an appropriate empirical antibiotic in the immunocompromised patient. Discussion with local microbiology services is recommended but expanded empiric coverage for Gram-negative organisms, including *Pseudomonas aeruginosa* may be warranted. When the organism has been identified and sensitivity results are available, it will probably be necessary either to change or to rationalise the antibiotics being given. [10] Meningitis caused by Gram-negative organisms is rare but multidrug resistance amongst Enterobacteriaceae is increasing. [4] If there is a high suspicion that an extended-spectrum beta-lactamase organism might be present then meropenem 2 g IV 8-hourly should be given (instead of a cephalosporin with or without amoxicillin/ampicillin).

In all cases, it is important to monitor the clinical response; antibiotics should be reviewed and appropriately altered once antibiotic sensitivities are known or if a patient is not improving. A repeat CSF examination should be performed if there is concern about antibiotic sensitivity or selection. In those with penicillin-resistant pneumococcal meningitis, a CSF examination 48 hours after presentation is recommended to ensure bacteriological improvement. Antibiotics should be given for 5 days for *N. meningitidis* ; 10–14 days for fully sensitive *S. pneumonia* ; and 21 days for *L. monocytogenes* . Intrathecal antibiotics are not recommended.[4]

Steroid Administration

The benefit of steroid administration in adult meningitis has been debated, but clear guidance is now available to support its routine use as the Cochrane Database of 4121 adults and children demonstrated significantly lower rates of hearing loss and neurological sequelae in those treated with corticosteroids.[11] Decreased mortality was only observed in those with pneumococcal meningitis. Concern remains that corticosteroids may reduce CSF penetration of antibiotics, although this has not been demonstrated in studies conducted in humans. For reasons that remain unclear, these effects are only observed in high-income countries with multiple studies showing no benefit to adjunctive corticosteroid therapy in low-income settings.

Recommendations in Adults

Dexamethasone 10 mg is an adjuvant treatment and should be given in adults IV shortly before or with the first dose of antibiotics and continued 6-hourly for 4 days. Dexamethasone should be halted if a microbiological cause for meningitis other than *S. pneumoniae* is identified.[4]

Anticonvulsants

Focal or generalised seizures should be treated immediately with IV benzodiazepines to stop the seizures, with subsequent IV loading with phenytoin or levetiracetam. The possibility of the following should be considered:

- raised ICP
- cerebritis
- cerebral abscess
- septic venous thrombosis.

The development of seizures may be indicative of a poor prognosis.

Intracranial Pressure

Intracranial hypertension is a common complication of meningitis. ICP monitoring may be required and standard measures such as hyperventilation, mannitol infusion or CSF drainage should be considered. Depending upon the particular circumstance, serial lumbar punctures or external ventricular drainage should be implemented.

General Management Considerations

Critical Care

Intensive care teams should be involved early in patients with rapidly evolving rash, evidence of limb ischaemia, cardiovascular instability, acid/base disturbance, hypoxia, respiratory compromise, frequent seizures or altered mental state. Patients with a rapidly evolving rash, GCS ≤12 (or a drop of >2 points), those requiring monitoring or specific organ support or those with uncontrolled seizures should be transferred to critical care facilities. [4]

Normal haemodynamics should be maintained. Inappropriate antidiuretic hormone secretion may occur in meningitis. Those with severe shock or profound coma may require a secure airway and respiratory support. Intubation should be strongly considered in those with a GCS of less than 12. Attention should be paid to the management of the unconscious patient with appropriate mouth and eye care. Physiotherapy will be required to prevent the onset of pressure sores. Surgical evaluation may be needed for skin necrosis. [12, 13]

Public Health

Meningitis prophylaxis is recommended for close (kissing contacts) associates and for those medical personnel with close contact in cases of probable or confirmed meningococcal meningitis only. Ciprofloxacin 500 mg po stat should be given to adults (alternative rifampicin 600 mg twice daily for 2 days). [4] Meningococcal vaccination may also be considered. Procedures should be in place to alert the infectious disease team and public health authorities. In many countries, the latter is a statutory obligation for the treating physician.

Prognosis

Untreated bacterial meningitis is usually fatal. Appropriate therapy significantly reduces the mortality rate, but studies still show that the overall mortality is approximately 18%. Mortality is slightly higher in those who have seizures when there have been delays in introducing treatment, and if the patient is either elderly or very young (see Table 63.3). [13, 14]

Cryptococcal Meningitis

Cryptococcus neoformans is a yeast that can cause chronic meningitis that is clinically similar to tuberculous meningitis. It is most frequently found in those who are immunocompromised, such as with HIV infection. A lumbar puncture should be obtained if the diagnosis is suspected, and the opening pressure should be measured. India ink evaluation and cryptococcal antigen testing can help establish the diagnosis, but culturing the organism from the spinal fluid remains the gold standard. Serum cryptococcal antigen testing is useful for the evaluation of patients with HIV infection, although a negative result cannot be used to rule out cryptococcal meningoencephalitis. Initial treatment is with amphotericin B and 5-fluorocytosine followed by consolidation therapy with fluconazole.

Management of the raised ICP may necessitate daily lumbar punctures or CSF diversion.

Viral Meningitis

The majority of cases of viral meningitis are benign, usually self-limiting conditions that are often caused by enteroviruses (which include Coxsackie viruses), herpes simplex virus (HSV) type 2 and varicella-zoster virus (VZV). In endemic regions, some are caused by arthropod-borne viruses (arboviruses), such as the West Nile virus. The same viruses that produce meningitis can also cause encephalitis. HSV type 1 usually produces encephalitis but rarely causes meningitis. Other viruses causing CNS infections include echoviruses, mumps, Toscana virus and HIV (particularly at the time of seroconversion). Patients with migrainous headaches often receive a lumbar puncture to rule out viral meningitis, which paradoxically may prolong their hospital stay with a post-lumbar-puncture headache and migraine.

Clinical Presentation

Patients usually present with symptoms of meningeal irritation, fever, headache, neck stiffness, retrobulbar pain, photophobia, vertigo, nausea and vomiting that are less severe than those with bacterial meningitis. The presence of intellectual impairment, focal neurological symptoms or seizures suggests that the brain parenchyma is involved often due to meningoencephalitis. A detailed travel history should be obtained, as this may alter the differential diagnosis in terms of the likely organism. True viral meningitis develops over hours to days but rarely lasts longer than 7–10 days. Occasionally it can have a thunderclap presentation. A variety of associated symptoms, such as nausea, vomiting and generalised malaise, may accompany this condition. [15]

Investigations

A CSF examination is important and usually shows:

- a mild-to-moderate lymphocytic pleocytosis (can be neutrophilic initially)
- a mildly elevated CSF protein concentration
- normal glucose concentration
- normal CSF lactate.

Staining for microorganisms, including bacteria, *Mycobacterium tuberculosis* and cryptococci is necessary. Sites for viral culture include the mucous membranes, throat, skin and rectum.

Management

Acute viral meningitis is usually a self-limiting condition, and only supportive therapy is required with analgesia and bed rest. Viral meningitis caused by HSV or VZV may require IV acyclovir, especially where it occurs in the immunosuppressed. Acute HIV infection causing meningitis responds to antiretroviral therapy.

Encephalitis

Encephalitis refers to inflammation of the brain. When secondary to an infectious organism, it can be caused by direct infection or by post-infectious, immune-mediated mechanisms. Autoimmune encephalitis can also occur independent of infection. HSV type 1, the most common and serious cause of focal encephalitis, usually affects the temporal and frontal lobes. There are a large number of arboviruses that cause epidemics of encephalitis. Encephalitis acts as a sentinel for new and emerging infections, including Japanese encephalitis, Nipah virus, Hendra virus, a variety of bat-associated viruses as well as West Nile and some tick-borne encephalitides.

West Nile virus is now the most common cause of epidemic viral encephalitis in some countries. Although, on neuroimaging, changes in the basal ganglia may suggest the diagnosis, a CSF pleocytosis may be a more obvious diagnostic finding. Although WNV-specific PCR is available, serology is more sensitive and detection of IgM antibodies in the serum or CSF is diagnostic. In patients with congenital or acquired humoral deficiency, however, nucleic acid amplification tests may be sometimes necessary to establish the diagnosis due to impaired antibody production.

There are also a variety of antibody-mediated encephalitides that target synaptic proteins. These include *n* -methyl- d -aspartate receptor (NMDAR) and subunits of the voltage-gated potassium channel complex.[16] Occasionally the former can be a sequela of HSV encephalitis. Clinicians should suspect autoimmune encephalitis in cases of subacute encephalopathy and prominent new-onset psychiatric disturbances. New-onset medically refractory epilepsy, including cryptogenic status epilepticus, as well as movement disorders, such as orolingual dyskinesias, dystonia and myoclonus can also be clues. Although the onset of neurologic symptoms in autoimmune encephalitis can sometimes be preceded by a viral prodrome, including fever, fever is not usually a predominant feature at presentation.

Clinical Presentation

The key clinical pointer to encephalitis is the presence of focal neurological symptoms indicating involvement of brain parenchyma. In particular, the presence of speech disturbance, seizures, altered cognition and disturbance of conscious level suggest this.

Diagnosis can be difficult.

- Abnormalities in cranial imaging such as T2-weighted magnetic resonance imaging (MRI) may support this diagnosis (Fig. 63.2).
- Electroencephalogram (EEG) studies may show slow-wave activity or epileptiform discharges in the temporal lobe. The presence of an extreme delta brush pattern is specific for NMDAR encephalitis. EEG may also exclude non-convulsive status epilepticus that can mimic or be a complication of encephalitis.
- PCR examination of the CSF examination may confirm the virus, although serology is generally more sensitive in immunocompetent patients with WNV and other arthropod-borne encephalitides.

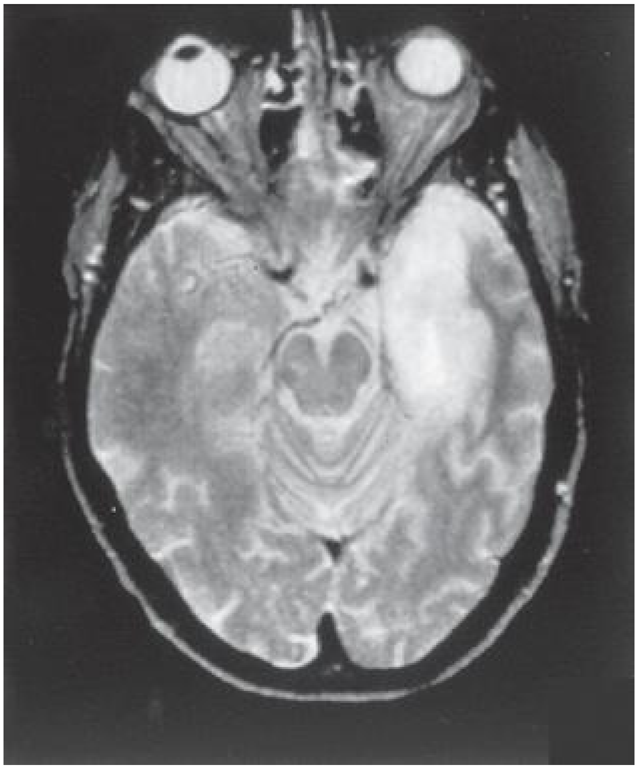


FIG. 63.2 Temporal lobe following herpes simplex encephalitis.

A systematic approach to the investigation of those with encephalitis has been proposed and national guidelines developed to reduce the proportion of unidentified cases. [17]

Treatment

Understanding, and if at all possible, identifying, the specific aetiological cause of an individual's encephalitis may ultimately have the greatest influence on the successful management of individual patients. [18]

Specific treatment for HSV encephalitis requires IV aciclovir at a dose of 30 mg/kg per day in three divided doses for at least 14 days; some recommend repeating the lumbar puncture, ensuring that the CSF is HSV DNA negative before halting aciclovir. [17] Untreated, the mortality of HSV encephalitis is approximately 70% but there is still 10%–20% mortality in patients treated with optimal therapy, and patients can be left with significant disability due to cognitive dysfunction or seizures. Most patients with significant cerebral oedema receive empirical steroids, although there are no clinical trials to support this therapy. Aciclovir can cause renal impairment and the patient should be hydrated intravenously, and renal function monitored. [19] Aggressive treatment of seizures is important.

CMV infection requires antiviral therapy with ganciclovir or valganciclovir. CMV can cause ganglionitis and polyradiculitis, which may suggest this diagnosis clinically in an immunocompromised patient.

Most CNS viruses cause neuronal damage but chronic John Cunningham (JC) virus infection in oligodendrocytes causes the syndrome of progressive multifocal leucoencephalopathy (PML). This condition presents with a subacute onset of confusion, weakness and visual symptoms, usually in an immunosuppressed individual. The MRI scan is usually suggestive but CSF examination with PCR amplification of the JC virus DNA may be required. Currently, no specific therapy for PML exists. Initiation of combined antiretroviral therapy in HIV patients with associated PML significantly improves survival but can be associated with paradoxical clinical worsening due to transient inflammation, a phenomenon known as immune reconstitution inflammatory syndrome (IRIS). [20]

Viral infection with HIV, measles and rubella can also cause chronic CNS infection leading to chronic encephalitides. *Mycoplasma* infection can give rise to post-infectious encephalitis.

A number of systemic neurological conditions (e.g. lymphoma, Lyme disease, sarcoidosis and vasculitides such as Behçet disease) may present with aseptic meningitis. It is therefore important to consider these systemic conditions in those presenting with viral meningitis or encephalitis.

First-line therapies for autoimmune encephalitis, include intravenous corticosteroids, intravenous immunoglobulin (IVIg), plasmapheresis, or a combination of these. Early initiation of immunotherapy is associated with improved outcomes. IVIg and plasmapheresis are probably safe alternatives in patients where there remains uncertainty between infectious and autoimmune encephalitis.

Tuberculous Meningitis

Meningitis caused by *M. tuberculosis* (TBM) has a variable natural history with a range of different clinical presentations. It typically affects adolescents and young persons but is not restricted to these age groups. It is more frequent in the immunosuppressed. This and the lack of specific and sensitive tests hinder the diagnosis of this condition. Approximately 10% of individuals with TB develop meningeal involvement. A variety of risk factors such as HIV, diabetes mellitus and recent use of steroids increases the risk of tuberculous meningitis. [21]

Clinical Features

TBM has a very varied clinical presentation. Often, it is heralded by a non-specific prodromal phase, frequently but not necessarily including headache, vomiting and fever. Of one case series that included those admitted to an intensive care unit, only 65% had fever, 52% had focal neurology and 88% had signs of meningism. A variety of cranial nerve palsies can occur, but other presentations include those seen with stroke, hydrocephalus and tuberculoma.

Diagnosis

An investigation of the differential diagnosis of TBM is important. Large-volume CSF samples should be taken (5 to 10 mL) to increase the sensitivity of acid-fast bacilli smear and mycobacterial culture. The use of PCR amplification of mycobacterial DNA can increase sensitivity further, and some of the newer assays such as the Xpert MTB/RIF, can provide information regarding antibiotic resistance. [22] CSF analysis shows an elevated protein, lymphocytic pleocytosis and hypoglycorrhachia. Those who are immunosuppressed can have an atypical CSF appearance, including normal CSF examinations in occasional HIV individuals. TB culture from CSF is required but may take up to 6 weeks before a positive culture result is available. Imaging studies may show basal meningitis and hydrocephalus, but these features are non-specific. [23]

Current advice suggests that in adults the first 2 months of treatment should comprise quadruple therapy:

- Isoniazid oral/IV 300 mg daily

- Rifampicin oral/IV 450 mg (<50 kg) and 600 mg (≥50 kg)
- Pyrazinamide oral 1.5 g (<50 kg) and 2 g (≥50 kg)
- Ethambutol oral 15 mg/kg

Fluoroquinolones (moxifloxacin or levofloxacin) may represent an effective fourth agent. Streptomycin is used rarely. Agent toxicity must be monitored in terms of renal and liver function and its effect on other organs, such as the eye. It is strongly recommended that advice is sought from local experts or networks with experience in the management of TB.

Corticosteroids are recommended in HIV seronegative patients with TBM. The initial steroid dose is guided by the patient's GCS and is tapered over 4–6 weeks.[24], [25] There is increasing multidrug-resistant tuberculous meningitis, especially in the HIV-positive population, reiterating the importance of culturing *M. tuberculosis* from clinical specimens to obtain sensitivities. Patients with TB meningitis frequently deteriorate over the weeks following initiation of appropriate chemotherapy and steroid regimens. Neurosurgical intervention for the treatment of hydrocephalus is sometimes required.

Subdural Empyema

This is a collection of pus between the dural and arachnoid space and usually is a consequence of middle ear or sinus disease. It may follow cranial osteomyelitis related to previous neurosurgery. Head trauma can also be responsible.

Individuals present acutely with headache, fever, neck stiffness, seizures and focal neurological symptoms. Meningeal signs and evidence of hemispheric dysfunction with sinusitis should suggest the diagnosis.

Diagnosis

Although CT and MRI are both effective in demonstrating a fluid collection, MRI provides additional information that can help distinguish infection from other sources of subdural fluid collections such as haemorrhage.

Surgical intervention, drainage and appropriate antibiotic regimens are required. Both Gram-positive (*S. aureus* and *Streptococcus* species) and Gram-negative organisms may be implicated. Initial broad-spectrum (Ceftriaxone 2 g IV 12-hourly and metronidazole 500 mg IV 8-hourly) cover should be narrowed to targeted treatment when the organism or organisms are known.

Prognosis

This condition if left untreated is invariably fatal. With treatment, mortality is in the order of 20% but neurological sequelae are common.

Epidural Infection

Cranial and spinal epidural abscess is an infection between the skull or spinal column and dura often as a consequence of osteomyelitis or malignancy. There is an occasional incidence following epidural anaesthesia. It is similar to subdural empyema. The organism involved where a catheter or drain is implicated is often the same as that found in the skin; hence, *S. aureus* is frequently responsible.

Presentation

Inflammation is commonly (but not always) present on the back and is usually generalised to the area of the back involved. There may be local tenderness over the site associated with redness of the catheter insertion site. Fever is common. Initially, mild neurological deficit may rapidly progress leading to para/quadriparesis.

Blood cultures may be positive and may indicate the organism.

Diagnosis

MRI is more sensitive to detecting epidural infections, especially in the spine. If unavailable, CT with contrast, along with spinal myelography should be considered. CT and MRI are both effective in diagnosis.

Spinal decompression and drainage are urgently required. This is usually a nosocomial infection and therefore resistant organisms are commonly found. Antibiotics should be specific for the organisms involved and may need to be continued for prolonged periods, often weeks, to eradicate the infection.

Where there have been neurological symptoms and signs prior to surgery, residual deficit is common. In one series, the recovery rate for patients with paresis/plegia after a lumbar epidural abscess was 50%, whereas no patients with paresis/plegia following a thoracic abscess recovered. The majority of long-term survivors had severe neurological deficits.

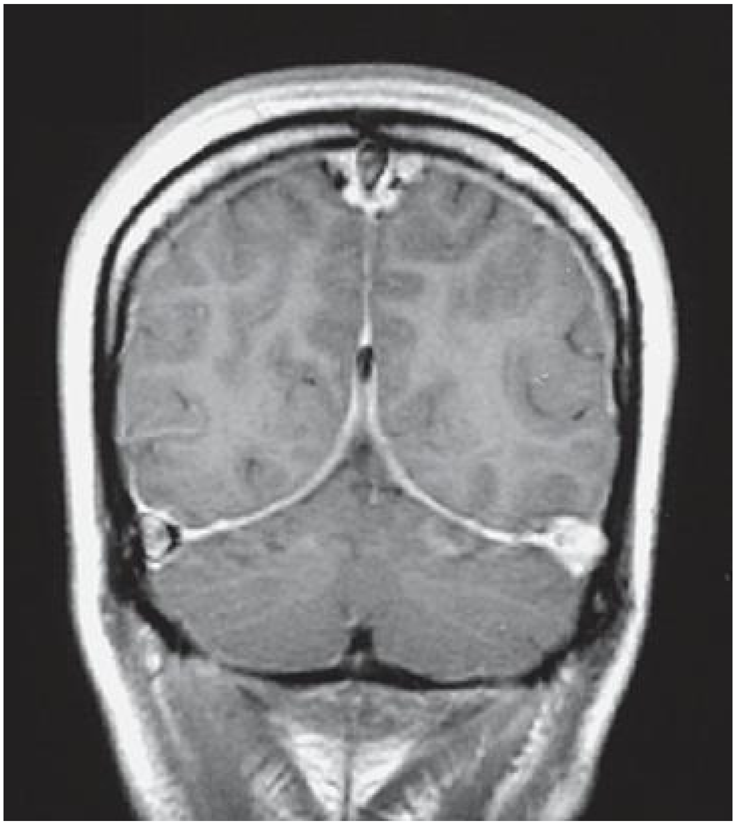
Cerebral Venous and Sagittal Sinus Thrombosis

Venous and sinus thrombosis may occur in the context of infection – in particular meningitis, and epidural or subdural abscess. It may also be secondary to facial or dental infection. It may have no septic aetiology but can occur either as an isolated event or in association with prothrombotic problems such as diabetic ketoacidosis, 3,4-methlenedioxymethamphetamine (MDMA) (ecstasy) abuse, oral contraceptives and hereditary prothrombotic conditions in pregnancy. [26]

Clinical signs at the presentation include:

- headache
- focal neurological deficits in particular cranial nerves
- seizures
- papilloedema.

The diagnostic sensitivity of CT, MRI and digital subtract angiography is 59%, 86% and 100%, respectively, but MRI with magnetic resonance angiography or CT venography reaches 96% (Fig. 63.3).



The magnetic resonance imaging depicts superior sagittal sinus thrombosis in coronal T1-weighted post-contrast view, with visualisation of thrombus formation within the sinus, venous outflow obstruction, and associated structural alterations in brain parenchyma.

FIG. 63.3 Magnetic resonance imaging (MRI) of superior sagittal sinus thrombosis: coronal T1-weighted post-contrast MRI; patient developed a sinus thrombosis following protracted labour and delivery.

Treatment

- Treat the primary infection if present.

- Anticoagulants are the mainstay of treatment. Paradoxically there are often areas of intracerebral haemorrhage in patients with sinus thrombosis. The presence of such haemorrhages is not a contraindication to anticoagulation.

Brain Abscess

Aetiology

Direct spread from bone or dura or may be via haematogenous spread. Predisposition includes cranial trauma, neurosurgery, chronic ear or sinus disease, suppurative lung disease, congenital heart disease and recurrent sepsis. Immunological compromise may predispose to more exotic organisms, but more common organisms include *S. aureus* (associated with local and haematogenous) spread; and *Streptococcus* spp., *Bacteroides fragilis* and Gram-negative bacteria, which are common with lung disease or recurrent sepsis.

Presentation

Severe headache, vomiting, obtundation, seizures and focal neurological signs. Neck stiffness is often absent. Clinical sepsis may not be obvious.

Diagnosis

- An obvious primary source of infection
- Evidence of raised ICP
- Focal cerebral or cerebellar signs.

Investigations

- Lumbar puncture is low yield and potentially dangerous if there is a significant mass effect

- CT scan with contrast will usually show a ring-enhancing lesion (Fig. 63.4)
- MRI
- Assessment of the patient’s immune status
- Blood cultures
- Echocardiogram – where infective endocarditis is suspected
- Specific blood tests such as HIV and toxoplasma serology.

B

The two magnetic resonance images depict a brain abscess with pre-contrast image presenting a hypodense lesion and post-contrast image displaying ring enhancement surrounding the lesion.

FIG. 63.4 Abscess: (A) pre-contrast and (B) post-contrast.

Treatment

Indications for surgery include large single lesions, relief of raised ICP and the need for tissue diagnosis.

Antibiotics are the mainstay of therapy. If the organism is known, then the treatment should be specific. In the absence of a definitive organism, ceftriaxone 2 g IV 12-hourly *or* cefotaxime 2 g IV 6-hourly *with* metronidazole 500 mg IV 8-hourly. If there is a recent history of trauma or neurosurgery, then a regimen that will cover *Staphylococcus* should be used. Antibiotics should be continued for 3–6 weeks.

Supportive therapy limits morbidity, which is nevertheless high. Mortality from cerebral abscesses is still 10%–20%. [27]

Lyme Disease

This is a tick-borne multisystem disease with dermatological, cardiological, rheumatological and neurological effects caused by the spirochaete *Borrelia burgdorferi* .

A history of potential exposure should be sought but is not always found. The disease may present in a variable fashion neurologically including as a cranial neuropathy (commonly a facial palsy) or as meningoencephalitis or radiculopathy. It may also cause lymphocytic meningitis and may have been diagnosed as ‘viral’ meningitis in the past. A variety of longer-term neurological sequelae have been described. [28]

Investigations

Cerebrospinal Fluid

White cell count is equivocal but may be raised. Protein is normal or marginally raised and sugar is normal or marginally low. Demonstration of intrathecal production of antibodies against *B. burgdorferi* via a CSF anti-*Borrelia* species IgG index comparing antibody levels in serum and CSF establishes the diagnosis. PCR has very low sensitivity, as well as low positive and negative predictive value.

Treatment

Practice parameters for the treatment of nervous system Lyme disease state that nervous system infection responds favourably to penicillin, ceftriaxone, cefotaxime and doxycycline. The optimal duration of treatment is not known, but 10–21 days is recommended. [29] Prolonged treatment with antibiotics appears to have no benefit in preventing post-Lyme syndrome.

Other Diseases

There are several other diseases that may have an encephalopathic component. Cerebral malaria is dealt with elsewhere. *Legionella* may lead to subclinical or clinical neurological manifestations, ranging from headache to coma or encephalopathy usually seen in conjunction with pneumonia, in addition to possible renal impairment. Similarly, *Mycoplasma* has been associated with an encephalitic picture characterised by impaired consciousness and seizures, and by normal or non-specific neuroradiological findings. Occasionally, symmetrical lesions in the putamen and its external surrounding areas have been seen.

Septic Encephalopathy

Septic encephalopathy has been described as a common complication in the critically ill, presenting in a panoply of ways, from the agitated confused state seen in acute sepsis to profound loss of consciousness. The aetiology is almost certainly multifactorial involving changes in cerebral blood flow, alteration in oxygen extraction, cerebral oedema, disruption of the blood–brain barrier, the presence and effects of diverse inflammatory mediators and abnormal neurotransmitter activity; deranged liver and renal function contribute. It is a syndrome of exclusion based on observation and circumstantial evidence. The EEG is usually abnormal with decreased fast activity and an increase in slow-wave activity, but the findings are not pathognomonic. There are no specific treatments. In general terms, the outcome appears to correlate with the management of the underlying sepsis.[30]

Neuromonitoring

Toby Jeffcote, Xiuxian Pham and Andrew Udy

Introduction

Critical illness is characterised by dynamic changes to physiological function that develop rapidly and unpredictably. These features have made monitoring of organ system function and dysfunction an integral part of intensive care unit (ICU) management. The reliance of ICU clinicians on these monitoring modalities means that a working knowledge of how these signals are generated and interpreted is essential to safe practice. Monitoring is particularly important in neurocritical care as many of the pathologies managed in the ICU require high levels of sedation which directly impairs clinical examination and assessment.

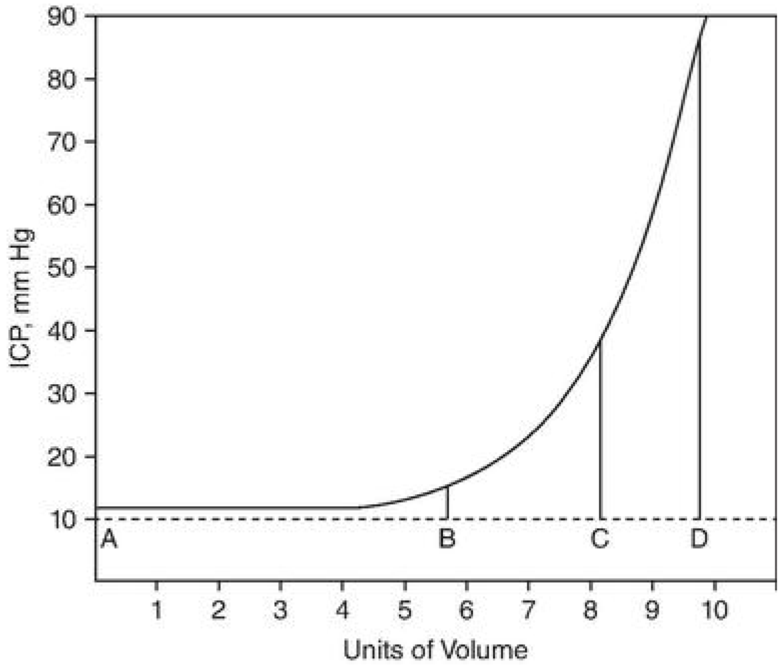
This chapter is organised according to the neuromonitoring requirements for specific pathological entities. The majority of the chapter will focus on the two most common forms of acquired brain injury encountered in the ICU, namely traumatic brain injury (TBI) and sub-arachnoid haemorrhage (SAH). We also provide relevant information on pathological entities that require specific forms of neuromonitoring such as status epilepticus (SE) and hypoxic ischaemic encephalopathy.

Monitoring in Traumatic Brain Injury

Traumatic brain injury (TBI) is a term used to describe injuries resulting from the application of force to the brain. TBI is a heterogeneous class of injuries and may include brain contusion, intra-cranial haemorrhage, traumatic sub-arachnoid haemorrhage and diffuse axonal injury either alone or in combination. The primary aims of the clinical management of TBI are the provision of optimal conditions for tissue recovery and the avoidance of secondary injuries associated with the pathophysiological evolution of the original injury. These goals may be difficult to achieve given that various sequelae of acute TBI will significantly disrupt the homeostatic mechanisms of the brain. These sequelae include, but are not limited to, raised intra-cranial pressure, derangements of cerebral autoregulation, brain tissue hypoxia, tissue metabolic distress, inflammation and electrophysiological abnormalities.

Monitoring Intracranial Pressure

Increases in intracranial pressure are commonly seen in the ICU management phase of moderate to severe TBI. These increases result from a complex interplay of factors with tissue oedema, hyperaemia, compromised CSF drainage and the presence of intra and extra-axial haemorrhage all contributing to increases in ICP. Some pressure buffering capacity is provided by the displacement of CSF from the intra-cranial compartment into the lumbar cistern (illustrated by the initially gradual increase in pressure on the ICP-volume curve seen in Fig. 64.1). [1] Once this buffering capacity is exhausted, ICP will increase in a near-exponential manner with any further increase in any of the constituents of intra-cranial volume.



The diagram depicts the pressure-volume relationship described by the Monroe-Kellie doctrine with stages of baseline intracranial volume and pressure, pressure buffering by cerebrospinal fluid displacement, exhaustion of buffering capacity, and rapid increases in intracranial pressure. The vertical axis shows intracranial pressure in millimetres of mercury, ranging from 10 to 90. The horizontal axis shows units of volume, ranging from 1 to 10. A curve moves upward from approximately 10 millimetres of mercury, labelled A, to 90 millimetres of mercury at 10 units, labelled D. A point at 20 millimetres of mercury at 6 units and 40 millimetres of mercury for 8 units are labelled as B and C, respectively.

FIG. 64.1 Pressure volume relationship described by the Monroe-Kellie doctrine. (A) Baseline intracranial volume and intracranial pressure. (B) Pressure buffering of volume increase by displacement of CSF into lumbar cistern. (C) Exhaustion of pressure buffering capacity leads to rapid increase in pressure with increased volume.

(D) Further increase in intracranial volume leads to rapid increases in intracranial pressure. (From Hickey JV, Olson DM, Turner DA. Intracranial pressure waveform analysis during rest and suctioning. *Biol Res Nurs* . 2009;11(2):174-186.)

Guidelines for ICP Monitoring

ICP monitoring was formally adopted by the Brain Trauma Foundation (BTF) in 1996. This decision was based on evidence that outcomes from severe TBI were significantly improved with the adoption of intensive management protocols aimed at the reduction of ICP when compared to uncontrolled intracranial hypertension. [2]

The BTF guidelines for the management of severe TBI recommend placement of an ICP monitor in TBI patients with a Glasgow Coma Scale (GCS) score less than 8 and either:

1. An abnormal computed tomogram (CT) scan of the head

Or when two or more of the following are present:

- Age greater than 40 years
- Unilateral or bilateral motor posturing
- Systolic blood pressure less than 90 mm Hg

The results of a consensus conference on ICP management [3] further extended these recommendations to include the following:

- Patients with an initial normal CT scan or with minor changes in CT images with features of neurologic worsening or progression on a repeat scan
- Evidence of brain swelling such as compressed or absent basal cisterns
- Patients with large bifrontal contusions independent of the neurological condition
- When sedation interruption to check neurological function cannot be safely performed, for example respiratory failure from lung

contusions and flail chest

- When the neurological examination is not reliable, for example maxillofacial trauma or spinal cord injury
- A decompressive craniectomy is performed as a last resort for intracranial hypertension refractory to medical management
- Following craniotomy for evacuation of a mass lesion in patients at high risk of brain oedema, for example pre-operative hypoxia, hypotension, pupil abnormalities and midline shift greater than 5 mm

Benefits of ICP Monitoring

The primary benefit of ICP monitoring in TBI is the ability to detect impending brain herniation syndromes resulting from expanding intra-cranial mass lesions, for example subdural haematoma. At extremes of intra-cranial pressure, major shifts in brain position can occur resulting in injuries to some of the most fundamentally important structures in the brain. However, even moderate increases in ICP can have adverse consequences for the patient as they can compromise cerebral blood flow.

The relationship between ICP and cerebral blood flow is best described as analogous to Ohm’s law which states that flow (Q) is proportional to the gradient between inflow and outflow (ΔP) divided by the resistance to flow (R) such that:

$$Q = \Delta P / R$$

$$CBF = (MAP - ICP) / R$$

Ohm’s law as applied to cerebral blood flow: MAP= mean arterial pressure, ICP=intra-cranial pressure.

In terms of cerebral blood flow, the gradient between inflow and outflow is termed the cerebral perfusion pressure (CPP). This is effectively the gradient between the mean arterial pressure (MAP) and the pressure in the cranial venous outflow system. Given the thin-walled structure of cerebral veins, this venous pressure is largely determined by intra-cranial pressure. It follows that CPP can be calculated as MAP – ICP, and that an increase in ICP will lead to a corresponding decrease in cerebral blood flow.

External Ventricular Drain (EVD)

Measurement of ICP was first utilised in the 1950s [4], [5] using an external ventricular drain (EVD) inserted into the frontal horn of the lateral ventricle. The pressure within the cranial vault determined the height of a column of fluid directly connected to the brain’s ventricular system. This pressure was directly measured with a bedside manometer and recorded via analogue transcription methods. The zero point of the manometer or pressure transducer was in line with the Foramen of Monro at the level of the external auditory meatus of the ear in the supine position. [6] Modern iterations of the EVD are typically impregnated with an antibiotic coating to reduce device-related infections and analogue transcription has been replaced by electronic pressure gauges and computer readouts.

Intraparenchymal ICP Monitors

Intraparenchymal ICP monitors are placed in the brain parenchyma, typically in the right frontal lobe, via burr hole access. Various devices are available, although the most commonly utilised in the Australian and New Zealand clinical context is the Codman ICP probe (Integra Lifesciences). This consists of a miniature strain gauge pressure sensor mounted in a Titanium case at the tip of a 100 cm 3F flexible nylon tube. This provides clinical data in the form of both a mean pressure reading and an ICP waveform.

	External ventricular drain	**Parenchymal ICP probe**
Placement	Placement usually performed with reference to anatomical landmarks. TBI may disrupt normal anatomy leading to misplacement	Straightforward to insert but potential for failure to breach the dura when inserted via burr hole
Measurement	Measurement of global ICP – gold standard measure	Readings may vary depending on head position and local pathology
Complications	Complications include placement-associated parenchymal haemorrhage, [7] catheter blockage and monitor-related infections (ventriculitis) [6, 8, 9]	Probes typically resistant to physical damage and have a low reported incidence of infection and insertion-related haemorrhage [10]
Advantages	Provides therapeutic option of draining CSF to reduce ICP	No requirement for pressure transducer adjustment with position changes

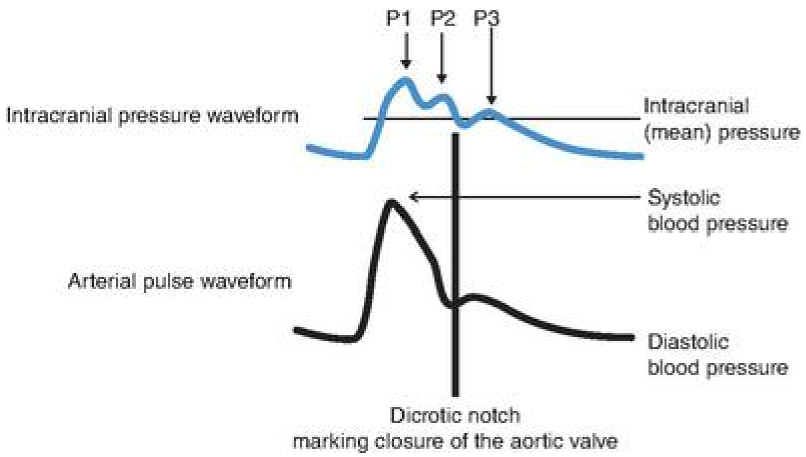
Definitions of Intracranial Hypertension and Thresholds of ICP

There is no universally accepted threshold defining intracranial hypertension. Various proposed ICP thresholds are quoted in the literature and the BTF guidelines identify a threshold of safe ICP as below 22 mm Hg. [11] It is important to note that this threshold is largely based on retrospective data investigating the relationship between ICP and poor outcomes. The adoption of other advanced monitoring modalities has led to an increasing realisation that safe ICP thresholds are likely to be both patient-specific and dynamic in nature in keeping with the evolving pathophysiological mechanisms of TBI. It may be that ICP is most effectively utilised as a means of calculating CPP rather than an absolute measure of pathology and that ‘permissive intracranial hypertension’ may be well tolerated so long as CPP is maintained and other markers of brain physiology can be referenced to guide management and ensure adequate perfusion, oxygenation and metabolic function. [12, 13]

The ICP Waveform

There are three main components to the ICP waveform (Fig. 64.2) [14] :

1. Pulse waveform, associated with the cardiac cycle (typical heart rate 50–180 bpm)
2. Respiratory waveform, associated with the respiratory cycle (typical respiratory rate of 8–20 cycles/minute)
3. Slow vasogenic waveform, associated with the autonomically mediated slow variation in cerebrovascular tone (typically 0.3–3 cycles/minute)



P1
P2
P3
Intracranial pressure waveform
Intracranial (mean) pressure
Systolic blood pressure
Arterial pulse waveform
Diastolic blood pressure
Dicrotic notch marking closure of the aortic valve

The first wavelet labelled Intracranial pressure waveform shows three peaks, labelled P 1, P 2, P 3. The average height is labelled intracranial mean pressure. The second wavelet is labelled arterial pulse waveform, with a peak labelled systolic blood pressure. The lowest point of the wavelet is labelled diastolic blood pressure. A vertical line, labelled Dicrotic notch marking closure of the aortic valve, intersects the wavelet.

FIG. 64.2 Temporal association of ICP wavelets with the arterial blood pressure trace. (From Hickey JV, Olson DM, Turner DA. Intracranial pressure waveform analysis during rest and suctioning. *Biol Res Nurs* . 2009;11(2):174-186.)

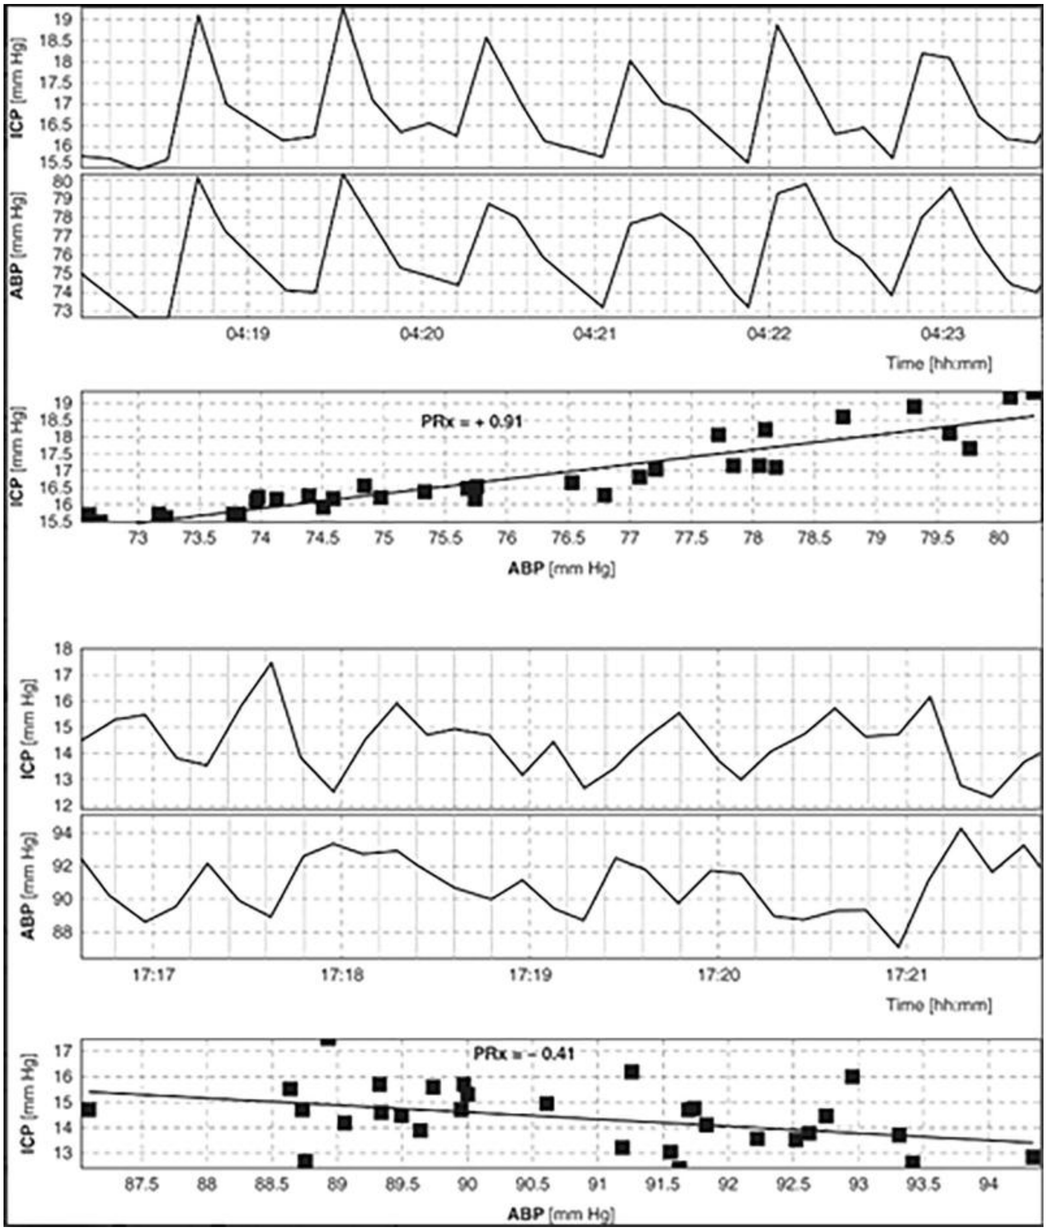
Pulse Waveform

The pulse waveform represents the volume and pressure changes transmitted to the cerebral tissues by the brain's arterial blood supply. An analysis of the pressure waveform over time reveals a characteristic fine structure with every pressure pulse comprised of at least three wavelets identified on the time axis from left to right as P1, P2 and P3.

The P1 or 'percussion' wavelet/peak result is generated by the expansion of the arterial walls due to the arriving arterial pulse. The P2 or 'tidal' wavelet is generated by the blood bolus from the elastic recoil of the cerebral arteries – a process analogous to the Windkessel effect seen in the aorta and other elastic systemic arteries. The height of the P2 wavelet represents the pressure–volume response to this bolus in terms of the compliance of the brain parenchyma. A small P2 indicates rapid absorption of the bolus volume by a highly compliant parenchyma. Reducing parenchymal compliance will be reflected by an increasingly elevated P2 wavelet. The P3 or ‘dicrotic’ wavelet is temporally associated with the dicrotic notch of the arterial pulse waveform and has a physiological association with cerebral venous outflow.

The Pressure Reactivity Index (PRx)

First proposed in 1997 [15] the pressure reactivity index was devised as a means of estimating the status of cerebrovascular autoregulation in acute brain pathologies. The method uses specific data sampling rates to select the slow frequency components of ICP and arterial blood pressure and calculates a correlation coefficient between the two variables within a moving time window. Low correlation between the two values indicates that ICP does not co-vary with changes to systemic arterial blood pressure. A high correlation coefficient indicates that ICP co-varies with values of systemic blood pressure and indicates a disruption of normal autoregulatory function (Fig. 64.3). [16]



The diagram with six panels depicts arterial blood pressure and intracranial pressure traces with correlation coefficients between consecutive samples. A correlation coefficient of zero point nine one indicates disrupted cerebral autoregulation, while a negative zero point four one indicates intact cerebral autoregulation during data analysis.

FIG. 64.3 Arterial blood pressure (ABP) and intracranial pressure traces and associated correlation coefficients between 30 consecutive 10 second samples of each data stream. Correlation coefficient of 0.91 indicates disrupted cerebral autoregulation. Correlation coefficient of −0.41 indicates intact cerebral autoregulation. (From Adapa R, Gupta AK, Gelb AW. *Gupta and Gelb's Essentials of Neuroanesthesia and Neurointensive Care* . 2nd ed. Cambridge, United Kingdom; New York, NY: Cambridge University Press; 2018.)

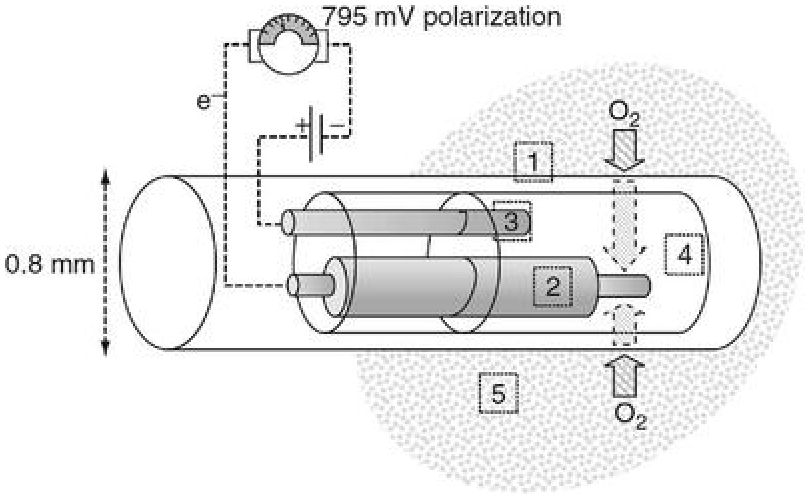
Since the advent of PRx evidence for an association with disrupted cerebral auto-regulation and poor outcome has accumulated, with threshold values of >0.05 associated with poor outcome and >0.25 associated with mortality. [17] The relationship between cerebral auto-regulatory status and outcome is non-linear and there is increasing evidence that the combination of high ICP and disrupted auto-regulation has a particularly strong association with poor outcome. [18]

Monitoring Brain Tissue Oxygen in TBI

Ischaemia and hypoxia play significant roles in the development of secondary brain injury in TBI. Histopathological studies first demonstrated this phenomenon some 30 years ago [19] and these findings remain evident in recent studies of patients managed with protocolised goal-directed TBI care. [20]

Brain tissue oxygen monitoring involves the placement of monitoring probes in the brain parenchyma to obtain a direct measure of the partial pressure of oxygen in the extracellular space surrounding the probe. Measurement techniques based on the Clark principle and on oxygen-sensitive optical dyes are both used in clinical practice. The Clark electrode-based technique consists of two electrodes in electrolyte solution housed in a protective cover. Oxygen diffuses across a permeable membrane window to contact the gold polarographic cathode inducing a flow of electrons directly proportional to the oxygen concentration in the parenchyma and extracellular fluid. The optical technique utilises wavelength analysis of oxygen-induced photochemical reactions to estimate local oxygen concentration.

The most commonly used system is a combined temperature and brain tissue oxygen catheter, attached to a Licox monitor (Integra Lifesciences Ltd). This probe combines a Clarks electrode (reading surface area = 18 mm^2, oxygen sensing length 7 mm)[21] and a thermocouple for internal calibration of readings to brain temperature (see Fig. 64.4).



The diagram depicts the Licox Clark electrode for brain tissue oxygen monitoring, including protective covering, gold working electrode, silver chloride reference counter electrode, ionic solution, and brain parenchyma, representing structural components involved in cerebral oxygen tension measurements.

FIG. 64.4 Licox Clark electrode for brain tissue oxygen monitoring. (1) Protective covering. (2) Gold working electrode. (3) Ag/AgCl reference/counter electrode. (4) Ionic solution. (5) Brain parenchyma. (From Nortje J, Gupta AK. The role of tissue oxygen monitoring in patients with acute brain injury. *Br J Anaesth* . 2006;97(1):95-106.)

PbtO$_2$ probes can be placed at the conclusion of surgery or via burr hole access. PbtO$_2$ probes placed via burr hole are typically secured using a single or multi-lumen cranial access device or ‘bolt’.

Normal Values for Brain Oxygen Levels

PbtO$_2$ values are a measure of tissue oxygenation in the region surrounding the probe and readings primarily reflect the relative proliferation of arterial and venous vessels in the immediate vicinity. Under normal conditions, arterial PO$_2$ is approximately 90 mm Hg and venous PO$_2$ is approximately 30 mm Hg. The normal value of PbtO$_2$ reflects the fact that 70% of the cortical vasculature is venous and is in the region of 40 mm Hg.[22]

There is no universally accepted PbtO$_2$ threshold for ischaemia.[22] This partly reflects various methods of defining ischaemia and the dynamic nature of ischaemic thresholds according to tissue metabolic demands. The most commonly quoted ischaemic tissue oxygen values derived from positron emission tomography (PET) scanning data are equivalent to between 10 and 15 mm Hg[23] and a value of 8.5 mm Hg translates to 50% SjVO$_2$.[24] Acknowledging the complexities surrounding a definition of ischaemia, PbtO$_2$ values <5 mm Hg are associated with cell death.[25]

Methodological Issues with Clinical Monitoring of PbtO$_2$

PbtO$_2$ readings are a dynamic reflection of systemic oxygenation, global and local cerebral blood flow and the balance of oxygen supply and demand in local tissue. The function and dysfunction of upstream organ systems and the manipulation of artificial organ supports, for example the fraction of inspired oxygen (fiO$_2$) will all have profound effects on PbtO$_2$ levels.[26] Cerebral tissue is extremely metabolically active at baseline and this activity will further increase in certain physiological and pathophysiological states (e.g. activation of specific brain regions associated with cognition, epileptic seizures[27] and cortical spreading depolarisation).[28] These factors alongside local tissue conditions, for example oedema/contusion must be considered as potential confounders influencing PbtO$_2$ readings. Recommendations for probe placement in TBI include placement within the sub-cortical white matter in the hemisphere with the highest burden of disease.[29] It is also crucial to perform CT imaging of probe placement and interpret PbtO$_2$ readings in the context of local tissue conditions.[12]

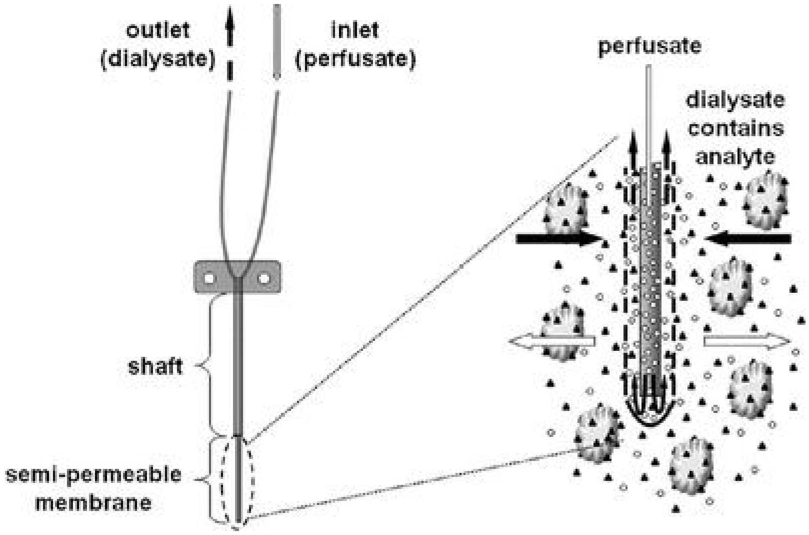
Studies of PbtO$_2$-based Management in TBI

The recently completed Brain Oxygen Optimisation in Severe TBI Phase II (BOOST-2) study[30] was a two-arm, single blind prospective randomised controlled study conducted in 10 ICUs in the United States, comparing care based on PbtO$_2$ readings with standard management. The trial was stopped early by the Data and Safety Monitoring Board for 'efficacy in the primary outcome' after 122 subjects (target sample size 182). There was also a signal for improved clinical outcomes in the PbtO$_2$ group, although the study was not powered to detect differences in these outcomes.

This encouraging result led to the development of additional trials of PbtO$_2$ monitoring in TBI (BOOST 3, BONANZA and OXY TC[31]), two of which are ongoing. These fit into an emerging picture of the benefit of PbtO$_2$-guided management of TBI, which has been reinforced by two confirmatory systematic reviews and meta-analyses of the available literature.[32, 33] Of note, however, OXY TC[31] did not demonstrate any benefit from PbtO$_2$ monitoring, and larger trials are required before any definitive conclusions can be made.

Cerebral Microdialysis in TBI

Cerebral microdialysis (CMD) is an invasive neuromonitoring technique that offers insights into cerebral metabolism in the aftermath of severe brain injury. CMD catheters consist of a dual lumen 'channel-within-a-channel' design. The distal 10 mm outer wall of the catheter consists of a semi-permeable membrane which allows the free diffusion of a variety of small molecules between the fluid volume within the catheter and the brain parenchyma surrounding the catheter. The catheter is perfused by a perfusate fluid of known electrolyte concentrations. This fluid is pumped down the outer channel of the catheter where it contacts the semi-permeable membrane at the catheter tip. Perfusion rates are slow (0.3 μL/min) and calibrated to optimise the equilibration of fluid and solute concentrations between brain parenchyma and microdialysis perfusate. The perfusate fluid then returns via the central catheter channel from which it is collected for analysis (Fig. 64.5).



The diagram depicts a parenchymal microdialysis probe where perfusate is pumped into the catheter past a semi-permeable membrane located in the brain parenchyma. Molecular exchange occurs across the membrane, and dialysate exits the catheter for further laboratory analysis in monitoring brain chemistry.

FIG. 64.5 Parenchymal microdialysis probe. Perfusate is pumped into the catheter and past a semi-permeable membrane sited in brain parenchyma. Molecular exchange takes place across this membrane and the resulting dialysate is pumped back out of the catheter for analysis. (©-free access image).

Microdialysate is collected manually in dedicated micro-vials and analysed hourly by the bedside using an enzymatic colourimetric analyser. This method provides hourly readings of glucose, lactate and pyruvate concentration from which the lactate-pyruvate (LP) ratio is calculated.

Microdialysis and Tissue Metabolism

The primary benefit of CMD is the provision of insights into the extracellular chemistry of cerebral tissue. Glucose is the brain's principal metabolic fuel, and CMD has demonstrated that both high and low levels of extracellular glucose are associated with worse outcomes after TBI. [34] The strongest argument for the use of CMD-derived biomarkers relates to the lactate-pyruvate ratio (LPR). The LPR reflects the $NADH/NAD^+$ redox status of the brain, that is, the balance between aerobic and anaerobic metabolism. [35] A high LPR indicates a high lactate production relative to pyruvate and the predominance of anaerobic metabolism. A high LPR is an independent predictor of poor patient outcomes. [36]

Given that there is no fixed level of $PbtO_2$ indicative of tissue stress secondary to ischaemia, the combination of CMD and $PbtO_2$ monitoring can identify tissue in which blood flow is insufficient to meet energetic demands. Clinical scenarios where a high LPR coincides with low $PbtO_2$ indicate anaerobic metabolism resulting from brain ischaemia (either an absolute ischaemia or an ischaemia relative to tissue demands). Clinical scenarios in which high LPR occurs in the setting of normal brain glucose concentration, normal cerebral perfusion pressure and normal or high $PbtO_2$, indicate cellular mitochondrial dysfunction. [37]

Neuromonitoring in Subarachnoid Haemorrhage

Subarachnoid haemorrhage (SAH) is a devastating disease with a hospitalisation rate of 14.5 per 100,000 per year in the United States and an overall case fatality rate of 25%–50%. [38]

80% of SAH results from the rupture of intra-cranial aneurysms. The initial release of arterial blood at systemic blood pressure results in a sudden increase in intra-cranial pressure and may also cause intra-parenchymal haemorrhage, brain shift and cerebral herniation syndromes. [39] The blood released from the aneurysm impairs the ability of arachnoid granulations to absorb CSF and may mechanically block CSF circulation through the ventricular system resulting in hydrocephalus, ventriculomegaly and raised ICP. Between approximately day 3 and day 21 following aneurysm rupture, patients are at risk of delayed cerebral ischaemia (DCI). The pathophysiology of DCI is characterised by a complex interplay of factors, including angiographic vasospasm, microvascular constriction, blood-brain barrier disruption, formation of microthrombi, inflammation and cortical spreading ischaemia. [39] This complication of SAH occurs in approximately 30% of SAH cases. [40] DCI and the cerebral infarctions that result from DCI are one of the most important indicators of adverse outcomes following SAH [41] and are an important focus of neuromonitoring techniques in SAH.

External Ventricular Drain

The external ventricular drain is commonly utilised in SAH but the rationale for its use differs from that of TBI. Raised ICP is not a consistent feature of SAH pathophysiology and maintenance of CPP is less problematic. EVD usage in SAH is primarily focused on addressing CSF build-up resulting from reduced CSF outflow from the ventricular system (obstructive hydrocephalus) and/or from the arachnoid granulations. EVD drainage can also reduce the volume of blood and associated blood breakdown products within the sub-arachnoid space. High concentrations of blood breakdown products such as free haemoglobin are closely associated with the risk of DCI. [42]

The management of CSF drainage in SAH differs between secured and unsecured aneurysms. Unsecured aneurysms carry a high risk of rebleed, and brain shifts associated with rapid changes to CSF volume are thought to increase rebleed risk. It is generally accepted practice to avoid over-drainage in unsecured aneurysms, although evidence for this approach is limited. [43] Once aneurysms are secured, the rationale for CSF drainage switches to CSF and blood product removal and drainage protocols tend to be more permissive. There is accumulating evidence of benefits associated with early EVD clamping and intermittent drainage in SAH. These benefits include a reduced incidence of blockage, EVD-related infection, requirement for ventriculo-peritoneal shunting and shorter length of stay. [44], [45]

Delayed Cerebral Ischaemia in SAH

DCI is a common complication of SAH which is strongly associated with poor outcomes. A high blood load in the sub-arachnoid space increases the likelihood of DCI. The release of vasoactive blood breakdown products is temporally associated with DCI and multiple mechanisms link these products with changes to the calibre and vasoreactivity of arterial vessels ranging from the major cerebral arteries to penetrating cortical arterioles. [42] It is important to emphasise the range of vessels involved in the pathophysiology of DCI as significant confusion can arise from imprecise nomenclature. A widely held view is that DCI results entirely from spasms of major cerebral arteries and the hypoperfusion that results from this reduced blood flow. This spasm of the proximal arteries does occur and can cause DCI. Importantly, DCI also occurs in the absence of proximal vasospasm and the process is best conceptualised as a process of acute ischaemia resulting from reductions in calibre of both the macro and microvasculature. From a clinical perspective, it is therefore important to monitor for both macro and microvascular ischaemia and treat both forms early to minimise DCI.

Transcranial Doppler Ultrasonography

Macrovascular or angiographic cerebral vasospasm (ACV) occurs in up to 70% of patients with SAH. [46] The gold standard examination for ACV is digital subtraction angiography but this is logistically difficult and associated with procedural risks. Other radiological alternatives for assessment include CTA and perfusion CT scanning but transcranial

Doppler (TCD) ultrasound is an attractive option due to its low cost, minimal invasiveness and bedside application. TCD ultrasound involves real-time measures of flow velocities in the major cerebral arteries. The relationship between flow velocities in different arteries provides important estimates of the calibre of these arteries which serve as markers of macrovascular cerebral vasospasm.

TCD Methodology

The major barrier to intracranial ultrasound is the dense bone of the skull. High-frequency ultrasound waves will not effectively penetrate this barrier, so the TCD examination is performed using a 2 MHz frequency ultrasound probe. In addition, the cerebral arteries are only accessible when ultrasound is transmitted through the thinnest regions of the skull. These ‘acoustic windows’ include the (1) transtemporal window, (2) transorbital window, (3) submandibular window and (4) suboccipital window. These technical issues mean that TCD examination requires a high level of skill and knowledge to perform accurately and may be subject to significant inter-observer variability.[47]

Ultrasound waves are transmitted through the skull and reflected by moving red blood cells within the insonated cerebral vessels. According to the Doppler principle, the difference in the frequency between the emitted and reflected waves, referred to as the ‘Doppler shift frequency’, is directly proportional to the speed of the moving red blood cells and is a measure of blood flow velocity within the cerebral arteries. The laminar nature of arterial blood flow means that the Doppler signal obtained is comprised of a mixture of Doppler frequency shifts. These signals are graphically represented as a spectral Doppler frequency display (Fig. 64.6). Standardised measures of blood flow velocity include peak systolic velocity (PSV), end diastolic velocity (EDV), pulsatility index (PI) and mean flow velocity (MFV). Mean flow velocity is a derived value calculated as $(\mathrm{PSV}+(\mathrm{EDV}\times 2))/3$.

(From Naqvi J, Yap KH, Ahmad G, Ghosh J. Transcranial Doppler ultrasound: a review of the physical principles and major applications in critical care. *Int J Vasc Med* . 2013;2013:629378.)

In summary, TCD is most effective for the identification of angiographic vasospasm in the MCA and BA. It is generally viewed as an adjunctive, non-invasive monitoring modality that is a useful guide as to the indication for cerebral angiography. It is important to recognise that serial examinations and the identification of trends will be more informative than isolated measurements and that all results must be interpreted in light of multiple technical and clinical variables, including ultrasound technique, vessel anatomy, mean arterial pressure, arterial CO_2 and haematocrit. [48]

TCD has been demonstrated to detect middle cerebral artery (MCA) and basilar artery (BA) vasospasm with high sensitivity and specificity. [49] The strongest evidence exists for the use of mean flow velocity in MCA with cut-off values able to predict the absence (MFV <120 cm/s) and presence (MFV >200 cm/s) of angiographic MCA vasospasm. [50] The Lindegard ratio (LR) (MCA MFV/extracranial ICA MFV) is a means of differentiating hyperdynamic cerebral blood flow from angiographic vasospasm with an LR of >3 indicating vasospasm but its use does not improve upon the identification of MCA vasospasm or DCI. [51] Whilst it is not possible to insonate the distal cerebral vasculature and obtain direct flow velocities, an increase in the pulsatility index indicates increased distal resistance and can be used as a surrogate measure of distal vasospasm.

Status Epilepticus and Seizure Disorders

Status epilepticus (SE) is a neurological emergency that commonly requires admission to the ICU. The International League Against Epilepsy (ILAE) operationally defined SE as convulsive seizure activity lasting greater than 5 minutes duration, or 2 or more seizures with incomplete recovery of consciousness between events. Refractory SE is defined as seizures that persist despite two antiseizure medications, typically an intravenous benzodiazepine and an intravenous longer-acting antiseizure medication.[52] Prolonged seizures result in cellular internalisation of post-synaptic GABA receptors (receptor trafficking) and the progressive development of pharmaco-resistance to antiseizure medications. There is, therefore, clinical benefit in aggressive termination of seizures and close monitoring for seizure recurrence.

The Electroencephalogram

The electroencephalogram (EEG) was first used to identify waveforms of brain electrical activity by Hans Berger in 1924. EEG recording involves the placement of multiple electrodes on the scalp to record the electrical signals generated by ionic current flows from synaptic transmission between cortical pyramidal neurons. Each electrode will detect variations in electrical current and contribute data to the EEG readout, which is a graph of electrical voltage difference between two electrodes. The most commonly utilised EEG array is the 10–20 system recommended by the International Federation of Clinical Neurophysiology (IFCN). Electrodes are spread across the scalp and separated by an anatomical distance of 10% or 20%. Each electrode is named with a letter and number according to scalp position (F = frontal, Fp = frontopolar, C = central, P = parietal, T = temporal, O = occipital)[53] (Fig. 64.7).[54]

The diagrams depict a ten-twenty montage and longitudinal bipolar referencing for neurophysiological monitoring. The ten-twenty montage presents standardised electrode placement, while the longitudinal bipolar referencing presents sequential connections across electrodes for capturing cortical electrical activity in clinical evaluations.

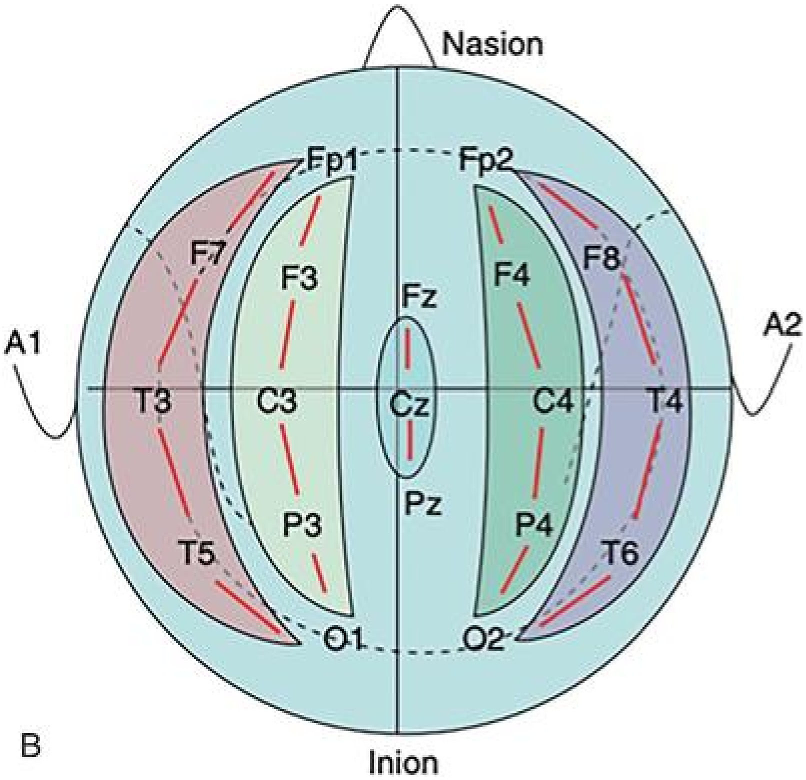

FIG. 64.7 (A) The 10–20 montage. (B) Longitudinal bipolar referencing in the 10–20 montage. (From Rossetti AO, Laureys S. *Clinical Neurophysiology in Disorders of Consciousness: Brain Function Monitoring in the ICU and Beyond* . Vienna: Springer; 2015.)

EEG in the ICU

EEG is useful for multiple clinical scenarios in the ICU, including unexplained or persistent coma, monitoring of acute brain injury and surveillance for electrographic seizure. Clinical factors must be considered when interpreting EEG in the ICU population. Severe pathologies such as sepsis and metabolic dysfunction may significantly alter EEG readings leading to misdiagnosis of CNS pathology. The use of sedatives and other medications may influence cortical activity and confound accurate EEG interpretation. Extremes of temperature and hypothermia may alter EEG readings and sequelae of cranial surgery, such as skull defects, must also be taken into consideration when interpreting EEG from ICU patients.

EEG Patterns and the Ictal-Interictal Continuum

Electrographic seizures are identified by repetitive epileptiform discharges at ≥2.5 Hz for ≥10 seconds, or any pattern with definite evolution of frequency, location or morphology and lasting ≥10 seconds. [55] It is, however, widely accepted that there is a spectrum of EEG activity encompassing normal patterns, abnormal but non-epileptic patterns and non-epileptic patterns that are closely associated with seizures and may evolve into seizures. This spectrum is termed the ictal-interictal continuum.

EEG for Status Epilepticus

Most epileptic seizures are self-limiting in nature. However, the mechanisms of seizure cessation are incompletely understood. Prolonged seizures are unusual, and the duration of the seizure is inversely proportional to the likelihood of spontaneous cessation. One retrospective analysis revealed that seizure duration of 10–29 minutes related to a cessation rate of 42%, whereas seizure durations of >30 minutes led to only a 7% cessation rate. [56] This ‘kindling’ effect underlies both the operational definition of SE as seizures of >5 minutes duration and the classification of SE as a medical emergency requiring early aggressive treatment.

Continuous EEG

Continuous EEG (cEEG) involves prolonged periods of EEG and video monitoring in the ICU and allows for accurate documentation of EEG over time and correlation with clinical manifestations of seizure. Continuous EEG has a number of benefits for the monitoring of SE but is costly in terms of set-up, maintenance and ongoing support by experts in EEG interpretation. The argument for cEEG in SE is strong given the clear pathological consequences of prolonged seizures. cEEG is becoming more accessible and is increasingly used for other acute brain pathologies such as TBI, and cEEG studies have revealed a relatively high incidence of electrographic seizures in both brain-injured and non–brain-injured patients in the ICU. [57]

Hypoxic Ischaemic Encephalopathy

Cerebral tissue relies on an uninterrupted supply of oxygen and metabolic fuel to maintain cellular function and integrity. The brain has no oxygen or glucose reserves, and interruption of supply will result in cellular damage within minutes, a process termed hypoxic ischaemic encephalopathy (HIE). Modern resuscitation practices have led to a greater proportion of patients surviving cardiac arrest and other events leading to an interruption of the blood supply to the brain, but survival is often characterised by variable degrees of neurological injury.

Cardiac arrest does not universally result in profound neurological injury and some patients recover neurological function rapidly. A large subset of patients has delayed neurological recovery following cardiac arrest. This group can be dichotomised into a group of patients who have suffered severe neurological injury incompatible with independent survival and a group characterised by variable degrees of neurological recovery occurring over extended periods of time. Accurately differentiating between these two groups has significant implications for informed family decision making on the issue of end-of-life care. It is also important in terms of resource allocation and distributive justice given the futility of providing extended ICU care to patients with no chance of neurological recovery. Several neuromonitoring modalities can aid prediction of neurological outcomes. Given the profound importance of accurate prognostication in this patient group and the many confounding factors that may influence neuromonitoring it is important that the results of diagnostic tests are interpreted in conjunction with other prognostic indicators.

EEG in HIE

Investigations into the use of EEG as an assessment modality post HIE have been complicated by variable assessment intervals post-resuscitation and the subjective nature of EEG interpretation. In addition, sedative drugs, metabolic disturbances, sepsis and the electrically noisy environment of the ICU all represent significant factors confounding accurate interpretation.

A number of ‘malignant’ EEG characteristics have been identified in HIE patients. These include complete or near-complete suppression, burst suppression, generalised periodic complexes, intermittent or continuous seizures, lack of reaction to stimuli and the alpha-theta pattern. These findings are associated with a higher mortality rate but have not been shown to be sensitive or specific predictors of poor neurological outcomes. [58] The EEG finding which most specifically predicts poor neurological outcome post-HIE is a global generalised suppression of EEG amplitude (<20 or <10 mV). [59]

Somatosensory Evoked Potentials and Neuroprognostication Post HIE

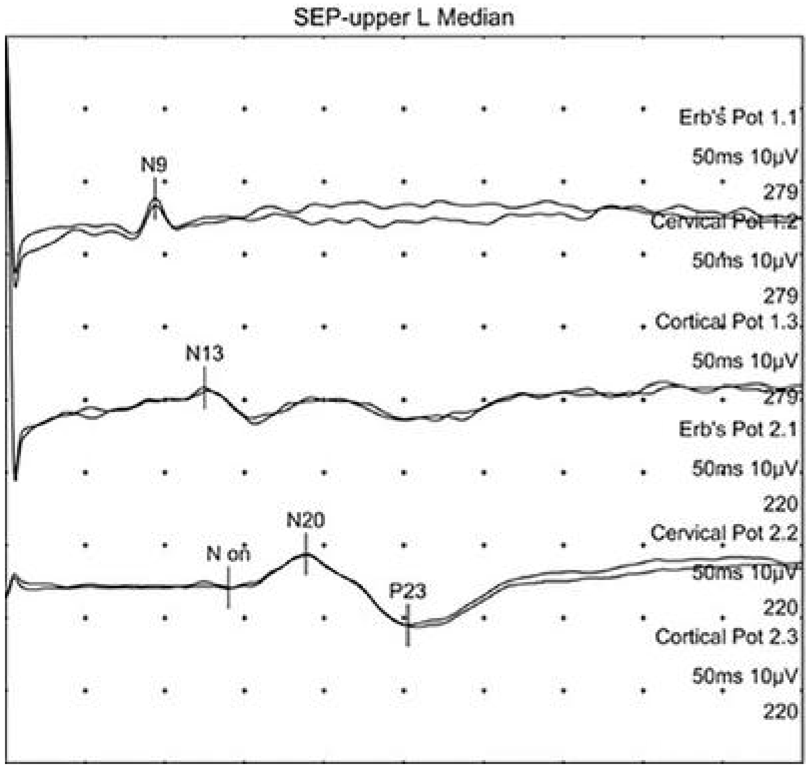
As discussed above, EEG signals result from cortical activity, EEG therefore has the ability to assess efferent functions of the brain and cortico-cortical connections post HIE. EEG does not, however, offer insights into thalamocortical connections in comatose patients. Somatosensory evoked potentials (SSEPs) are recordings of cortical responses to a peripheral stimulus and as such are a means of assessing the integrity and function of the dorsal column-lemniscal tract as it travels from the spinal cord to the cortex via brainstem, midbrain and thalamus.

Technical Considerations with SSEP

The most commonly utilised SSEP technique in the ICU context is the median nerve SSEP. The stimulus is delivered via two electrodes. The anode (positive electrode) overlies the wrist crease and the cathode (negative electrode) is sited 2 cm proximally. The electrical stimulus is a bipolar transcutaneous square wave electrical pulse of 100–500 microseconds duration at a stimulus rate of 3–5 Hz. Contraction of the thenar muscles is used as confirmation of correct placement and stimulus intensity (this should be just above the motor threshold). EEG electrodes are also placed at three points to track the transmission of the impulse:

1. Erb’s point: 2–3 cm above the clavicular head medial to the sternocleidomastoid muscle ipsilateral to the median nerve electrodes
2. Spinal electrode: placed over C5 or 6 spinous process
3. Cortical electrodes: parietal electrodes sited ipsilateral and contralateral to median nerve stimulus

The delivery of a stimulus to the median nerve produces a series of peaks at each of these electrodes. N9 is recorded at Erb’s point and indicates intact peripheral nerve function. N13 is recorded by the spinal electrode and represents the dorsal horn potential. N20 is recorded by the contralateral cortical electrode and is followed by a small positive deflection (P23). It is essential that N9 and N13 peaks are present to confirm peripheral and spinal transmission before interpretation of SSEP can take place (Fig. 64.8).



The diagram depicts normal median nerve generated somatosensory evoked potential illustrating deflections in E r b point channel as N nine, cervical channel as N thirteen, and contralateral cortical channel as N twenty and P twenty three, used for assessing neural pathway integrity.

FIG. 64.8 Normal median nerve generated SSEP illustrating deflections in Erb's point channel (N9), cervical channel (N13) and the contralateral cortical channel (N20 and P23). (From Rossetti AO, Laureys S. *Clinical Neurophysiology in Disorders of Consciousness: Brain Function Monitoring in the ICU and Beyond* . Vienna: Springer; 2015.)

Potential Confounders of SSEP in ICU

Several issues arise with the interpretation of SSEP in the ICU context. The ICU is an electrically noisy environment and a low signal-to-noise ratio has been shown to contribute to significant inter-observer variability in the interpretation of SSEP recordings. [60] The use of hypothermia as a neuroprotective measure following cardiac arrest may influence signal latency and amplitude in SSEP and examination should ideally be undertaken under conditions of normothermia. Cortical SSEP responses are relatively resistant to low-dose sedation and indeed sedation may improve SSEP quality in the setting of some abnormal EEG patterns. However, the use of high-dose sedation and barbiturate coma has been demonstrated to depress cortical SSEP. Similarly severe biochemical and metabolic disturbances should be corrected to ensure accurate SSEP interpretation. [54]

Prognostication Post-HIE

The bilateral absence of N20 SSEP responses more than 24 hours post-event is a robust indicator of poor outcome (defined as a failure to recover awareness) in unconscious patients post-circulatory arrest. Importantly the false-positive rate (FPR) for SSEP is as low as 0.007, with a 95% confidence interval of 0.001–0.047. [61] Conversely, bilateral preservation of the N20 is not necessarily an indicator of good outcome post cardiac arrest. Intact SSEP demonstrates the preservation of thalamocortical circuits, but HIE can result in a variety of patterns of neurological damage, including selective damage to cortical pyramidal cells which results in the abnormal EEG patterns described above. Investigations into the prognostic significance of mid-latency (N60) and late-latency (N70) SSEP responses are based on the idea that these responses represent complex cortico-cortical interactions modulated by the reticular activating system. There is emerging evidence that these responses have significant prognostic value [61] but further data are awaited. [62]

Conclusion

The clinical manifestations of neurological disease in the ICU are complex and multi-faceted. Conditions may be isolated to a single limb or affect the central nervous system and impact multiple organ systems. It is important to note that many of the patient-centred outcomes from neurological diseases managed in the ICU remain poor. These outcomes contrast with other areas of ICU care which have seen significant improvements in outcomes.

The aim of this chapter has been twofold. First to provide an overview of the major methods of neuromonitoring employed in the management of critically ill patients in the ICU. The review is intentionally broad, and this breadth prevents in-depth discussion of some particularly interesting areas of the topic where research and development are altering the landscape of care rapidly. Our second aim is to stimulate interest in the topic of neurocritical care. It is possible to improve outcomes from these diseases, but this can only be achieved by motivated critical care clinicians asking how we could manage these patients more effectively. With this in mind, we encourage the interested reader to review the reference section for further details.

Introduction

Delirium is an acute confusional state, common in critically ill patients. It is more often seen in patients with baseline cognitive dysfunction, and those with more severe acute illness. It is an independent predictor of mortality, hospital length of stay (LOS) and long-term cognitive impairment (LTCI).

There are few effective pharmacological interventions for the prevention and treatment of delirium, though their use in established hyperactive delirium may be occasionally required to ensure the safe care of patients and staff. Non-pharmacological interventions remain the mainstay of prophylaxis and therapy.

Definition

Delirium is a phenomenon so common to intensive care unit (ICU) that it is often considered an inevitable accompaniment to critical illness. However, despite its familiarity it is important to recognise it and to identify patients at risk of developing it at the point of admission to ICU, as effective prevention and treatment are possible and may improve patient outcomes.

The term delirium is, at its core, a social construction. As such, it is impossible to encapsulate it with a precise and enduring definition. However, a workable definition is crucial to enable the recognition, quantification and management of this clinical syndrome. With further research, what we currently recognise as one clinical entity is likely to constitute a multitude of pathologies, each with individualised treatments. The elusive *best* definition is likely to be a utilitarian one, that guides treatments which result in better patient outcomes.

The most comprehensive definition is that of the American Psychiatric Association's (APA) Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V). This defines delirium as a disturbance in attention, awareness and cognition that develops over a short period of time, is fluctuant and is associated with perceptual changes such as hallucinations (Box 65.1).[1] The definition is not specific to ICU and has slowly evolved with each edition. From a critical care perspective, the most relevant amendment to the 5th edition is the withdrawal of the use of the term 'consciousness'. It now excludes any such disturbances in the context of a reduced level of arousal, such as a comatose state. Omitting consciousness and shifting the focus towards attention and awareness is, at least in part, a reflection of the challenges of objective assessment of consciousness.

Box 65.1

DSM-5 classification of delirium

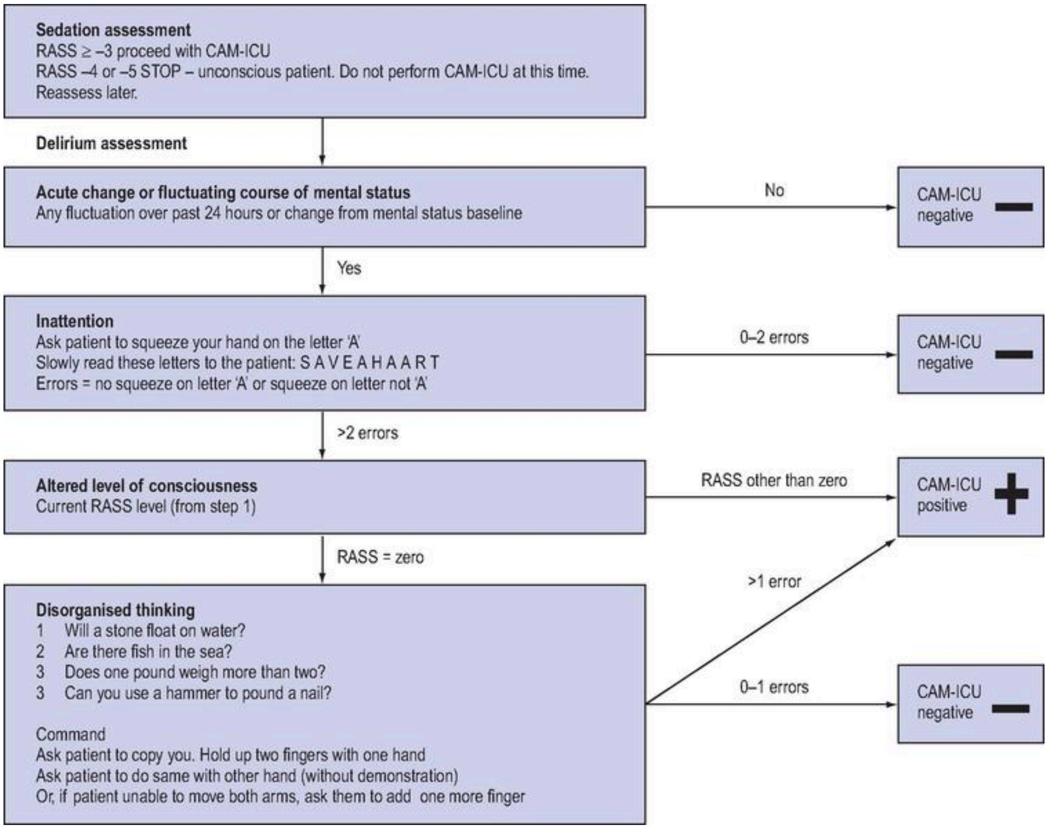
A	Disturbance in attention (i.e. reduced ability to direct, focus, sustain and shift attention) and awareness (reduced orientation to the environment).
B	The disturbance develops over a short period of time (usually hours to a few days), represents an acute change from baseline attention and awareness, and tends to fluctuate in severity during the course of a day.
C	An additional disturbance in cognition (e.g. memory deficit, disorientation, language, visuospatial ability or perception).
D	The disturbances in Criteria A and C are not better explained by a pre-existing, established or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal such as coma.
E	There is evidence from the history, physical examination or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal (i.e. due to a drug of abuse or to a medication), or exposure to a toxin or is due to multiple aetiologies.

The subcategorisation of delirium is usually approached through either clinical presentation or aetiology. Three clinical subtypes are recognised: hypoactive, hyperactive and mixed. The most common is hypoactive delirium, [2] associated in most studies with the worst prognosis. [3] This is often misdiagnosed as depression or sedation, or unrecognised altogether. Patients appear cooperative and docile but if formally assessed show signs of inattention and disorganised thinking. Conversely, hyperactive delirium is more readily apparent, but much less common. Patients can be agitated, uncooperative and combative; they are more likely to experience hallucinations. Hyperactive delirium must be distinguished from lucid agitation, which is often amenable to treatment of an underlying cause such as pain, urinary retention or fear. Mixed delirium describes patients that fluctuate between both states. Patients who have one or more symptoms of delirium but do not fulfil the full diagnostic criteria are referred to as having subsyndromal delirium (SSD).[4,5]

Consideration of delirium by aetiology may offer the benefit of compartmentalising patients into groups likely to respond to specific treatments. For example it is important to supplement B vitamin levels in delirium tremens, but not necessarily so for others. Hyperactive delirium might plausibly respond to medications with sedating effects, whereas this is unlikely to be true of hypoactive delirium. Failure to recognise this distinction might have been the reason many medication trials have not found benefit. However, as delirium is multi-factorial and poorly understood, categorisation by this approach is necessarily pragmatic. Groupings are based on readily identifiable components such as hypoxia, sepsis, sedation and metabolic dysfunction.[6] These phenotypic silos are not mutually exclusive, nor exhaustive and are likely to evolve in the upcoming years.

Screening

The most widely used screening tools in critical care are the Confusion Assessment Method for ICU (CAM-ICU) (Fig. 65.1)[7] and the Intensive Care Delirium Screening Checklist (ICDSC).[8] These aim to detect the key features of delirium: inattention, disorganised thinking, altered level of arousal and altered sleep pattern. They are designed and validated for clinical use to identify delirium in critically ill intubated patients. They do not rely on verbal patient responses, are simple to use and require minimal training. The CAM-ICU is a point-in-time assessment, whereas the ICDSC uses information gathered over a nursing shift.



Sedation assessment
RASS ≥ –3 proceed with CAM-ICU
RASS –4 or –5 STOP – unconscious patient. Do not perform CAM-ICU at this time. Reassess later.
Delirium assessment
Acute change or fluctuating course of mental status
Any fluctuation over past 24 hours or change from mental status baseline
No
CAM-ICU negative –
Yes
Inattention
Ask patient to squeeze your hand on the letter 'A'
Slowly read these letters to the patient: S A V E A H A A R T
Errors = no squeeze on letter 'A' or squeeze on letter not 'A'
0–2 errors
CAM-ICU negative –
>2 errors
Altered level of consciousness
Current RASS level (from step 1)
RASS other than zero
CAM-ICU positive +
RASS = zero
>1 error
Disorganised thinking
1 Will a stone float on water?
2 Are there fish in the sea?
3 Does one pound weigh more than two?
3 Can you use a hammer to pound a nail?
Command
Ask patient to copy you. Hold up two fingers with one hand
Ask patient to do same with other hand (without demonstration)
Or, if patient unable to move both arms, ask them to add one more finger
0–1 errors
CAM-ICU negative –

The decision diagram presents a structured pathway for conducting a delirium assessment using the Confusion Assessment Method for the Intensive Care Unit. It starts with a sedation assessment using Richmond Agitation Sedation Scale values. If the patient is eligible, the path continues to assess acute mental status changes, attention through letter recognition tasks, altered consciousness levels, and disorganised thinking through yes or no questions. Based on the criteria thresholds and scoring, the flow ends with C A M I C U outcomes marked as positive if greater than 1 error or negative if 0 to 1 error.

FIG. 65.1 Confusion assessment method for ICU (CAM-ICU) flow chart.

The ACCM/SCCM guidelines advocate either the CAM-ICU or ICDSC as the most valid and reliable screening tools for detecting and monitoring delirium in adult ICU patients. [9] These tools have high sensitivity (both 99%), specificity (CAM-ICU 47%–96%, ICDSC 66%) and inter-rater reliability. [8], [10], [11]

Historical Perspective

The first records of delirious patients are from Hippocrates in the 5th century BCE, who used the terms *phrenitis* (frenzy) and *lethargus* . This terminology reflected the belief that the diaphragm governed the seat of consciousness and thus phrenitis was the underlying pathology. [12] The word delirium itself is derived from the Latin *de* (away) + *lira* (furrow in a field), literally meaning *going away from the ploughed track.* It first appears in Da Medicina, a 1st century BCE treatise by Aulus Cornelius Celsus. [13]

Until relatively recently, delirious patients have been described as having acute brain failure, ICU psychosis or subacute befuddlement. [14] As per APA recommendations, the term ‘delirium’ is now uniformly employed in clinical practice to describe this condition of brain dysfunction.

Prevalence

There is a large variation in reported rates of ICU delirium. In part, this reflects the classic paradigm of intensive care research: heterogeneity in underlying pathology, treatment, comorbidity and illness severity. Accurate reporting has been hindered by ambiguity in disease definition, measurement frequency in a time-fluctuant disease and the challenges of communication with an artificial airway.

Historically, the subtle nature of hypoactive delirium has led to its gross under-recognition. In one study, nurses detected delirium in only a third of cases, and doctors in only a quarter. [15] In another, only a quarter of ICU staff were found to screen for delirium routinely. [16]

Despite these problems, the clear consensus is that delirium in the ICU is not only common but has the highest incidence of all areas in the hospital. Studies using the CAM-ICU or ICDSC highlighted the magnitude of the problem, with some reporting upward of 80% of mechanically ventilated patients experiencing delirium,[7] and rates about half of that in non-ventilated patients. Around a third of ICU patients experience SSD, however the prevalence varies widely depending on the cohort.[17]

Of ICU patients with delirium, mixed delirium is the most common subtype (55%), followed by hypoactive (44%) and hyperactive (2%).[2] According to aetiology, sedative-associated delirium has been reported as the most common, followed by hypoxic, septic and then metabolic.[6] Sedative-associated delirium appears to be unique, in that it is rapidly reversible and not associated with adverse long-term outcomes.

Pathophysiology

The pathophysiology of delirium is ill-defined. There are multiple competing theories regarding the cerebral changes that result in and from delirium. It can be induced by common problems such as rapid eye movement (REM) sleep deprivation, sedation, hypoxia, hypo/hyperthermia, hypo/hyperglycaemia, metabolic dysregulation and hypoperfusion. However, it can exist in the absence of these, and there is a spectrum of susceptibility that suggests we have an incomplete understanding.

These hypotheses are not specific to ICU cohorts, and it is unknown if ICU delirium is more common and more severe because it results from pathophysiological mechanisms distinct from those in ward patients, or purely due to the magnitude of inflammation encountered, and sedatives used.

Several mechanisms result in a common pathway of neurotransmitter imbalance and resultant cholinergic hypoactivity,[18,19] leading to a state of relative dopamine excess, which can also cause deterioration in attention or consciousness. This complex pathway is still being characterised, and the lack of response to anti-psychotic and anticholinergic medications has called into question its role in the causality of delirium. Other theories relate to the availability of tryptophan,[20] a metabolic precursor of serotonin, which may play a role since both increased and decreased levels of serotonin are seen in delirium.[21]

Genetics and epigenetics almost certainly contribute to a predisposition towards delirium, but this too is poorly characterised. Candidate genes such as apolipoprotein E4 (Apoε4) are being investigated.[22], [23] The wild-type (Apoε3), a recognised susceptibility factor for Alzheimer disease, results in impaired suppression of cerebral inflammation more than the other isoforms. Neuroinflammation is thought to be central to delirium, through tumour necrosis factor-alpha (TNF-α) activation of microglia, impaired oxidative metabolism, altered cerebral blood flow, increased blood–brain barrier permeability, thalamic dysfunction and aberrant levels of large neutral amino acids.[24-26]

Risk Factors

Mental state is a pyramidion, dependent upon the balance of all organ systems below it. The list of risk factors for delirium is non-exhaustive and includes any chronic conditions that result in cognitive impairment, as well as most homeostatic variables associated with critical illness. These can be divided into predisposing (non-modifiable) and precipitating (both modifiable and non-modifiable) risk factors (Table 65.1). They are cumulative,[7] and a frail patient may develop delirium from only a minor precipitating factor.

Table 65.1

The Pain, Agitation/Sedation, Delirium, Immobility, and Sleep (PADIS) guidelines state that the only two modifiable factors with strong evidence for an association with delirium are benzodiazepine use and blood transfusions. Non-modifiable factors with strong associations include: age, dementia, prior coma, emergency surgery or trauma pre-ICU and severity of acute illness (characterised by APACHE-II score) and comorbidity (characterised by ASA score).[27]

Other risk factors with strong evidence supporting their association with delirium include:

> mechanical ventilation, metabolic acidosis, multiple organ failure,
> delirium on the previous day and a history of hypertension.[28]

Prediction

The PRE-DELIRIC (PREdiction of DELIRium in ICu patients) model [29], [30] was developed to help predict the likelihood of developing delirium. It uses parameters readily available during the first 24 hours, such as age, APACHE-II score, admission diagnosis group, coma, infection, metabolic acidosis, use of sedatives and morphine, urea concentration and admission urgency. Using this model, the risk factors that confer the highest risk are coma (from any cause), infection and sedatives.

Pharmacological Prevention of Delirium

Patients are commonly sedated in the ICU for tolerance of endotracheal intubation and mechanical ventilation. One should consider which class and dose of sedative is most appropriate to the patient and their clinical condition. Most sedating drugs, including fentanyl and propofol, can precipitate delirium. Whenever sedating a patient, a protocol with routine sedation scoring tools such as the Richmond Agitation–Sedation Scale (RASS) should be used, alongside sedation targets. Some studies have found sedation reduces delirium, [31] but these results have not been replicated in other trials conducted in the context of routine light sedation. [32], [33] Deep sedation (e.g. RASS –3) in the first 48 hours of sedation and ventilation has been associated with increased time to extubation and mortality. [34] Unless there is a clinical reason to keep a patient sedated, a daily RASS target of 0 to −1 is appropriate.

Pain control in ICU is important. Although opioids can be deliriogenic, higher doses of opioids are associated with a significantly lower risk of delirium in a burns ICU population. [35] Avoiding GABA-ergic sedation entirely by using an opioid-based approach reduced mortality in an early single-centre trial, regrettably unable to be replicated subsequently in a multicentre study. [36] Many critically unwell patients are unable to report their own pain. Validated tools such as the Behavioural Pain Scale (BPS) and the Critical-Care Pain Observation Tool (CPOT) are useful for objective monitoring in these populations. [9]

Clonidine and dexmedetomidine are α2-adrenergic receptor agonists, the latter being more receptor-selective. They have a sedative effect independent of gamma-aminobutyric acid-ergic (GABA-ergic) activity, potentially reducing the requirements for deliriogenic GABA-ergic sedatives. Their side effect profile includes bradycardia and hypotension, and they should be used with caution in any patient requiring high levels of haemodynamic support. Care should also be taken if using in combination with other bradycardia-inducing agents.

Several large trials have found lower rates of delirium and superior associated outcomes with dexmedetomidine in comparison to alternative sedatives. Most recently, the SPICE-III trial found the median number of days that patients were free from coma or delirium and the median number of ventilator-free days were both 1 day higher in the dexmedetomidine group, but that this might be an age-dependent effect, with greatest effectiveness in patients >63.7 years of age and a suggestion of increased mortality in younger patients.[37] While dexmedetomidine was associated with more hypotension and bradycardia, in the most unwell patients (such as those with septic shock), dexmedetomidine if anything appears to increase blood pressure in comparison to alternatives, potentially by increasing sensitivity to α1 agonists. A subsequent meta-analysis has shown that its use may reduce delirium, duration of ventilation and ICU and hospital LOS.[38]

The HOPE ICU[39] and REDUCE[40] trials have shown that haloperidol is not effective in the prevention of delirium. There is some evidence that there may be a role for atypical anti-psychotics,[41] ketamine[42] and volatile agents.[43] However, this comes from individual trials in post-operative cohorts, does not confer a LOS or mortality benefit and may not be generalisable to other settings. They are not currently recommended in the PADIS guidelines, in part due to the frequency and morbidity of patients remaining on long-term anti-psychotics erroneously after ICU discharge.

Stopping a statin in critical illness is associated with an increased risk of delirium,[26,44] though there is no evidence that starting one pre-operatively reduces it.[45,46]

Ketamine's potential role in prevention was an unexpected incidental finding that requires further investigation.[42] It is, however, notorious for inducing psychiatric symptoms and is usually avoided in the treatment of hyperactive delirium. Although it may successfully induce a docile state, there is concern that patients may experience a worsening of their mental state. Like benzodiazepines, it is held in reserve for when other agents are contraindicated.

Pharmacological treatment of delirium

Studies of most pharmacological agents have found limited or no efficacy for the treatment of delirium, its associated increased LOS or mortality. Each drug class has a considerable side effect profile, notwithstanding paradoxical delirium. As such, the routine use of drugs in the management of delirium is not recommended in mainstream guidelines outside of a few special circumstances. Use of analgesia and sedatives for the control of pain, stress and anxiety should be weighed up for each patient individually and considered alongside, but separate from, the delirium itself.

Dexmedetomidine has been recommended in the PADIS guidelines for use in mechanically ventilated adults where agitation is preventing weaning and extubation,[27] based primarily on the results of one 15-hospital placebo-controlled trial limited to delirious, agitated patients.[47] A meta-analysis since then has shown that its use may reduce delirium, duration of ventilation and ICU and hospital LOS[38]; future guidelines may include a broader recommendation.

Haloperidol is a butyrophenone with partial selectivity for dopamine D_2 receptors. Haloperidol should not be given to patients with Parkinson's disease or those with a family history of dystonia. Side effects include sedation, autonomic effects, and extrapyramidal symptoms. Akathisia, an unpleasant sensation of restlessness, may be mistaken for continuing agitation. Neuroleptic malignant syndrome and torsades de pointes are both potentially life-threatening complications. QT_c prolongation increases the risk of torsades. Monitoring should be carried out prior to starting the drug, and daily thereafter. QT-prolonging drugs should be used with caution when the QT_c is greater than 450 ms, and not if greater than 500 ms. There is little trial evidence showing haloperidol resolves delirium more quickly or improves patient outcomes.[48]

Atypical anti-psychotics such as olanzapine, quetiapine and risperidone have a lower incidence of extrapyramidal side effects than haloperidol. Early evidence supporting quetiapine has been followed by large, randomised trials that have not shown atypical anti-psychotics to be associated with reduced duration of delirium, mechanical ventilation, ICU LOS, or mortality. Hence, their routine use is not recommended. [27] Failure of these trials to demonstrate benefit might be due to the heterogeneity of hyper- and hypoactive delirium patients enrolled. There may be a role in the treatment of anxiety, psychosis or to prevent the potential to harm themselves or others. Prescriptions should be for a limited duration with specified review dates.

The use of anticholinesterases, including rivastigmine, for the treatment of delirium in critically ill patients is not recommended and may be harmful. [49]

Aside from seizure prophylaxis in delirium tremens, the role of benzodiazepines in ICU is now reserved for circumstances when other agents are contraindicated, for instance, those patients with prolonged QTc and/or on high doses of inotropic infusions. This is supported by a Cochrane review. [50] A study investigating benzodiazepine in burns ICU patients showed they were seven times more likely to develop delirium. [35]

Non-Pharmacological Prevention of Delirium

Non-pharmacological interventions form the mainstay of delirium prophylaxis. Many of these are both simple and intuitive, though all too often omitted. Most are extrapolated from ward-based interventions where the evidence is stronger; applicability to ICU depends in part on the proportion of non-ventilated patients admitted. Examples include correcting audio and visual sensory impairments, and provision of cognitive stimulation. Promotion of a normal sleep-wake cycle and the avoidance of sleep deprivation can be achieved by minimising environmental noise, provision of earplugs [51] and reducing overnight disturbances from nursing, medication and procedural interventions. Family involvement is important and has been shown to reduce the psychological stress of kin. However, it does not reduce the incidence of delirium or its associated morbidity. [52]

Early mobilisation of critically ill patients has been demonstrated to decrease delirium and improve outcomes. [53] Impediments to mobilisation can be reduced through prudent removal of monitoring and lines, reduction in sedation and optimisation of analgesia. On the converse, physical restraints are known to increase the risk of delirium and should be avoided unless there is a clear risk of physical harm to the patient or staff that is not better managed in other ways.

Non-Pharmacological Treatment of Delirium

The core of delirium treatment is the prompt and appropriate treatment of the underlying disease and controlling the physiological sequelae of critical illness: febrile episodes, electrolyte and metabolic derangements, hypotension and hypoxia.

There is very little randomised trial evidence supporting non-pharmacological interventions for the treatment of established hyper- or hypoactive delirium. Nonetheless, measures outlined as prophylaxis all seem logical. For example orientation supported by environmental aids (e.g. visible clocks and windows); clear communication and frequent verbal cues (e.g. date, time and location), sleep hygiene and encouraging family involvement (providing a sense of control, familiarity and security). Family can also provide the clinician with collateral information regarding the patient's premorbid mental and functional status.

Integrated Delirium Prophylaxis and Treatment

There is evidence, primarily from before-after cohort studies, that implementing delirium bundles results in a reduction in delirium, ICU LOS, or overall mortality, [54-57] All the interventions encompassed in these bundles have an intrinsic plausibility and are essentially free from adverse events. One example is the A2F bundle, which is an approach to delirium care that aims to unify the core pharmacological and non-pharmacological strategies (Box 65.2). [58]

Box 65.2

A2F delirium bundle

A ssess, prevent and manage pain
B oth Spontaneous Awakening Trials (SAT) and Spontaneous Breathing Trials (SBT)
C hoice of analgesia and sedation
D elirium: assess, prevent and manage
E arly mobility and exercise
F amily engagement and empowerment

Beyond the doors of the ICU, many centres now offer follow-up clinics. One important use of this time is to listen to patients' recollections of their experience (or lack thereof). Distortions of time and reality, highlighted by traumatic hallucinations are common. Clinicians can help bridge the narrative of their illness and rationalise traumatic memories. [59] To the same end, many units advocate the use of patient diaries and photograph compilations, written by staff and relatives.

Collateral Impact

ICU admission is a distressing time for relatives of patients, exacerbated by witnessing their loved ones suffering from delirium. Reassurance that clinicians are vigilant to seek out and address treatable causes is helpful. It is good practice to counsel them that mental status changes in the ICU are common and usually transient but to caution them of the potential for LTCI. Information leaflets are a useful adjunct.

Prolonged shift work with agitated patients will also take a toll on nursing staff. Extended provision of care to the delirious can lead to staff exasperation. Delirious patients are unable to contextualise this behaviour and interpret exasperation as malice, become wary of the staff and are more reluctant to comply. This precipitates a negative feedback loop, all too often culminating in pharmacological sedation.

Prognosis

ICU delirium has long been identified as an independent predictor of longer hospital stays and mortality.[60-61] Revised estimates suggest this may be true only of those with prolonged delirium, that is, lasting more than one day.[62] Even in SSD, a single symptom has been associated with a significant increase in hospital LOS and functional decline, though less so than for those with full delirium. Compared with case-matched critically ill patients without delirium, those with delirium have a 6-month mortality that is three times greater.[61] Of the subtypes, hypoactive and/or mixed delirium has been associated with the highest mortality,[63], [64] though sedation-related delirium does not appear to confer an adverse mortality[65] . Each day spent in a delirious state has been associated with a 10% increase in the risk of death.[60], [61] It results in a threefold increase in the risk of discharge into long-term care[66] and a ninefold increase in the likelihood of experiencing LTCI.[61] In Alzheimer disease, delirium is associated with an acceleration in cognitive decline.

While the association between delirium and poor outcomes is clear, a causal relationship has yet to be proven. LTCI is likely the result of the underlying mechanism rather than the delirium itself. For example ‘hypoxic’, ‘septic’ and ‘unclassified’ delirium are associated with LTCI, but ‘metabolic’ delirium is not.[6] There is scarce evidence showing treatment of delirium will prevent LTCI, and it can still occur in patients who did not demonstrate delirium during their ICU admission.[67]

ICU-acquired weakness

Zudin Puthucheary and Carol L. Hodgson

Definition

Muscle weakness is a frequent problem in the intensive care unit (ICU). Muscle weakness can occur due to primary neuromuscular disorders (e.g. Guillain-Barré syndrome and motor neurone disease) or as a secondary disorder as a result of critical illness. [1] The latter is called ICU-acquired weakness (ICU-AW), which is an encompassing functional description of weakness that occurs due to critical illness. Over time more than 20 different terms have been used [2] until a definition framework was proposed [2] and later accepted [3] as part of clinical practice guidelines.

We currently consider all generalised new weaknesses with no alternative explanation to be ICU-AW. Three systematic reviews estimated the prevalence of ICU-AW to be between 33% and 46%. [3-5] In those with documented polyneuropathy and/or myopathy, sub-categories exist of:

- *Critical illness polyneuropathy (CIP):* Those with electrophysiological evidence of distal axonal polyneuropathy
- *Critical illness myopathy (CIM):* Those with electrophysiological and/or histological evidence of myopathy
- *Critical illness neuromyopathy (CINM):* Those with electrophysiological and/or histological evidence of CIM and CIP

Clinical Features

The classical features of ICU-AW are proximal muscle wasting and symmetrical flaccid weakness with absent reflexes. [6] The facial muscles are often spared. The presence of distal muscle weakness predominance suggests either an alternative diagnosis OR the presence of axonal damage (CIP or overlap). [7]

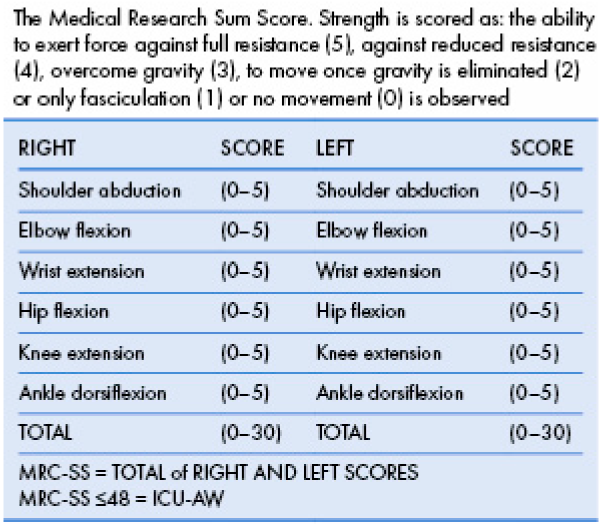
Diagnostic Criteria

Physical Examination

ICU-AW is diagnosed on physical examination using the Medical Research Council (MRC) Sum Score. The MRC sum score was first described in 60 patients with Guillain-Barré syndrome as an assessment tool, as part of the Dutch gamma globulin trial. [8], [9] A 90% inter-rater agreement (defined as <10% change in score) was seen in measurements between blinded observers. In 2002, this technique was deployed in a multi-centred observational study of 95 critically ill patients following 7 days of mechanical ventilation. [6] Patients were expected to respond appropriately to 3 of 5 questions, on 2 consecutive evaluations with a 6-hour interval, to be considered appropriate for manual muscle testing.

Each limb is scored using the MRC strength scale of 0–5 for proximal and distal muscle groups in regards to the muscle groups ability to exert force against full resistance (5), against reduced resistance (4), overcome gravity (3), to move once gravity is eliminated (2) or if only fasciculation (1) or no movement (0) is observed (Table 66.1), and the score for each limb added up (to a maximum of 60). An arbitrary cut off of 48 is used to distinguish weak patients.

Table 66.1

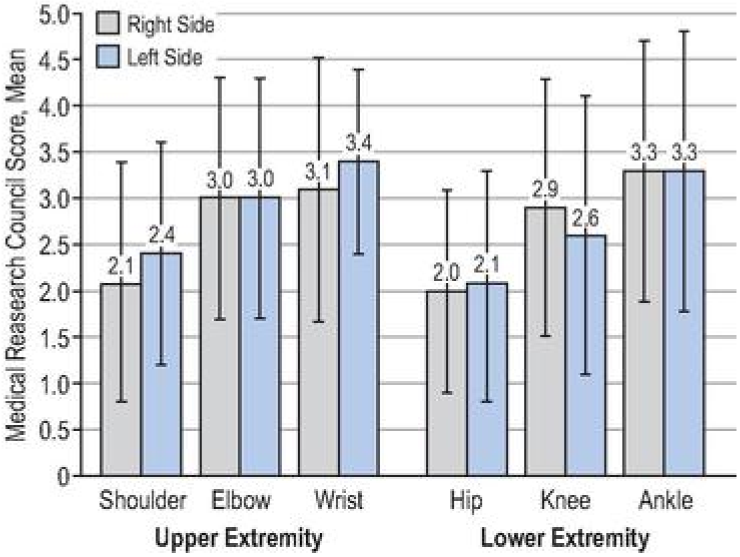


The Medical Research Sum Score. Strength is scored as: the ability to exert force against full resistance (5), against reduced resistance (4), overcome gravity (3), to move once gravity is eliminated (2) or only fasciculation (1) or no movement (0) is observed

RIGHT	SCORE	LEFT	SCORE
Shoulder abduction	(0–5)	Shoulder abduction	(0–5)
Elbow flexion	(0–5)	Elbow flexion	(0–5)
Wrist extension	(0–5)	Wrist extension	(0–5)
Hip flexion	(0–5)	Hip flexion	(0–5)
Knee extension	(0–5)	Knee extension	(0–5)
Ankle dorsiflexion	(0–5)	Ankle dorsiflexion	(0–5)
TOTAL	(0–30)	TOTAL	(0–30)

MRC-SS = TOTAL of RIGHT AND LEFT SCORES
MRC-SS ≤48 = ICU-AW

Several concerns exist as regards its clinical utility. While excellent inter-rater reliability has been seen in healthy subjects and critical illness survivors, this worsens considerably in the ICU setting. [10, 11] Furthermore, 30%–60% of patients have been unable to perform manual muscle testing when assessed. [6, 12] Proximal muscle wasting is extremely common [6] and of initial substantial functional importance, but is underrepresented in the MRC-Sum Score (Fig. 66.1). Finally, MRC-Sum score assessment can detect weakness once it occurs, but is unable to identify those *at risk.*



The bar graph represents Medical Research Council scores comparing right and left sides for six muscle groups. The horizontal axis lists body regions, including the shoulder, elbow, and wrist under upper extremity, and hip, knee, and ankle under lower extremity. The vertical axis ranges from zero to five. For each region, there are two vertical bars. One bar represents the right side and the other represents the left side. Shoulder and hip have lower scores at two point one and two on the right side. The elbow has equal scores at three. The wrist shows a slightly higher value on the left at three point four. The knee has a higher value on the right at two point nine. The ankle has equal scores for both sides at three point three. Error bars extend vertically from each bar, indicating variation in data. All six muscle groups show variation in strength, with upper extremity generally scoring higher than the lower extremity.

FIG. 66.1 Medical Research Score distribution in awake critically ill patients, demonstrating proximal muscle wasting. (From De Jonghe

B, Sharshar T, Lefaucheur JP, et al. Paresis acquired in the intensive care unit: a prospective multicenter study. *JAMA* . 2002;288(22):2859–2867.)

Electrophysiological Studies

Nerve conduction abnormalities have been demonstrated repeatedly in the critically ill patient, and were first described by Bolton in 1984. [13] Emerging hypotheses for the pathophysiology include acquired channelopathies of voltage-gated sodium channels, localising the defect to the muscle membrane. [14-16] In addition, neuronal tissue architecture disruption has been seen in peripheral nerve biopsies. [17] Quantification and description of these functional defects are done by nerve conduction studies (NCS) and electromyography (EMG). [18] Aside from the technical difficulties of performing and interpreting EMG in the critical care setting, their use in assessing the aetiology or severity of muscle weakness is limited by two factors. Firstly, EMG and NCS abnormalities appear universal in ICU patients and correlate poorly with the severity of muscle function loss. [6, 18-21] Secondly, lack of patient cooperation (for instance, due to sedation or pharmacological paralysis) prevents early detection of neuromuscular abnormalities and thus risk of weakness. [2] While severe neuropathy is debilitating, critical illness neuropathy is much less common than critical illness myopathy [4, 6, 22] and, again, correlates poorly with symptoms of weakness.

Electrophysiological studies are rarely performed in the acute setting. However, neurophysiology is essential for the diagnosis of peripheral nerve injury – both foot drop and entrapment syndromes are common and, untreated, can lead to functional disability. Further, it can be used to distinguish other less common causes of weakness that are unmasked by critical illness (e.g. motor neurone disease).

Criteria for sub-categories of ICU-AW described by Stevens [2] are as follows:

CIP:

- Compound muscle action potential amplitudes are decreased to <80% of the lower limit of normal in ≥2 nerves
- Sensory nerve action potential amplitudes are decreased to <80% of the lower limit of normal in ≥2 nerves
- Normal or near-normal nerve conduction velocities without conduction block
- Absence of a decremented response on repetitive nerve stimulation

CIM:

- Sensory nerve action potential amplitudes are >80% of the lower limit of normal) in ≥2 nerves
- Needle electromyogram in ≥2 muscle groups demonstrates short-duration, low-amplitude motor unit potentials with early or normal full recruitment with or without fibrillation potentials
- Direct muscle stimulation demonstrates reduced excitability (muscle/nerve ratio >0.5) in ≥2 muscle groups

Incidence

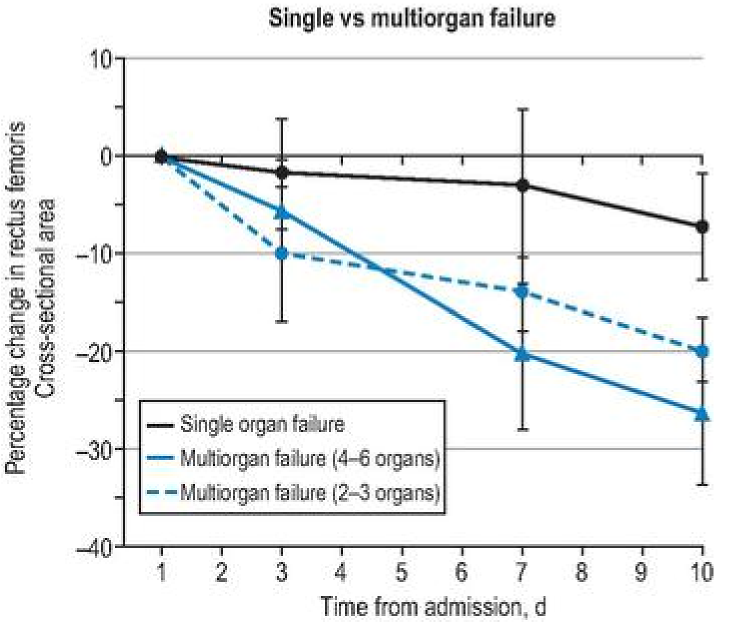
ICU-AW is the most common secondary complication of critical illness. Weakness at awakening can be detected in up to 65% of patients following 5–7 days of ventilation.[6], [23-25] This is unsurprising given that a 10% change in muscle mass has significant functional implications[26] and critically ill patients in multi-organ failure have muscle wasting at rates between 2% and 3% per day.[27], [28]

Understanding the incidence of CIP, CIM and CIMN is less easy as electrophysiological abnormalities are almost universally present in the acute critical illness phase[20] and bear an unclear relationship with the eventual clinical phenotype. Furthermore, the variation in diagnostic methodology and timings vary widely in the literature.[29]

Pathophysiology

Loss of Muscle Mass

Acute muscle wasting occurs rapidly and early in critical illness. Detectable muscle loss can occur within the first 72 hours. Several studies have suggested that wasting occurs at rates of 2%–3% per day of critical illness.[28] The severity of muscle wasting is directly related to the degree of illness severity – as more organs fail (SOFA score >2 within an organ system) more muscle is lost[27] (Fig. 66.2).



The line graph compares changes in muscle size over ten days in patients with single or multiorgan failure. The horizontal axis lists time in days from admission, ranging from one to ten. The vertical axis displays percentage change in rectus femoris cross-sectional area, ranging from negative forty percent to ten. Three lines represent separate conditions: single organ failure, multiorgan failure, one for involvement of four to six organs and one for two to three organs. All lines trend downward, indicating muscle loss. Steeper declines are associated with multiorgan failure. Vertical error bars extend from each data point. The graph reflects greater muscle degradation in patients with more extensive organ involvement across the observed period.

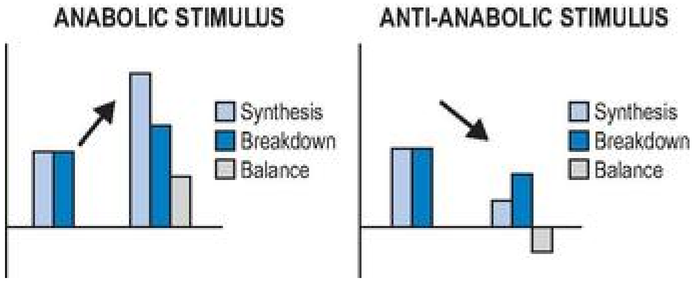
FIG. 66.2 Rates of skeletal muscle wasting by organ failure. Organ failure defined as cumulative Sequential Organ Failure Assessment (SOFA) scores. *d* , Day. (From Puthucheary ZA, Rawal J, McPhail M,

et al. Acute skeletal muscle wasting in critical illness. *JAMA* . 2013;310(15):1591–1600.)

Clinical drivers of muscle wasting have been noted to be the PaO_2 to FiO_2 ratio, and the degrees of acidosis and inflammation. In the only direct study comparing nutritional delivery to change in muscle mass, no interactions were seen with calories delivered, and increased protein delivery was associated with increased muscle wasting. [27] While controversial and should be seen as hypothesis generating currently, the ability of nutritional delivery to affect muscle mass remains contentious (see later).

Altered Protein Homeostasis

Skeletal muscle mass in all vertebral organisms is governed by the principles of protein homeostasis: a balance of muscle protein synthesis (MPS) and muscle protein breakdown (MPB). [30] The two processes are linked. In humans (in a completely different fashion from rodents), MPS has been repeatedly shown to be facilitative (the initial responsive process to a physiological stimulus) and MPB *adaptive* (responds to the change in MPS) by decreasing or increasing (but to a lesser amount) alongside MPS [31] (Fig. 66.3).



The schematic representation depicts differentiation of anabolic and anti-anabolic stimulus response in humans, showing regulatory signals under anabolic conditions that enhance protein synthesis via signalling pathways and under anti-anabolic conditions that activate protein degradation mechanisms leading to muscle protein catabolism and altered muscle mass.

FIG. 66.3 Schematic of the protein homeostatic response in humans to anabolic and anti-anabolic stimuli.

Within the critical care environment, patients are exposed to a variety of stimuli that affect this balance (Fig. 66.4).

The schematic representation depicts a seesaw with synthesis on one side and breakdown on the other side, with synthesis on the lower end. A table below shows two columns with the following headers: anabolism and catabolism, where synthesis is under anabolism and breakdown is under catabolism. The factors under anabolism are feeding, insulin, and exercise therapy. The factors under catabolism are inflammation, immobilisation and bed rest, and ageing.

FIG. 66.4 Factors affecting muscle protein homeostasis in critically ill patients.

Muscle protein homeostasis in the critically ill seems to be determined by the time course of illness. While several studies have conflicted as to the altered balance, the only longitudinal study demonstrated suppressed muscle protein synthesis on the initial day of critical illness, with variable recovery over the first week. [27] This decrease in MPS resulted in a greater MPB than MPS resulting in a net catabolic state that was mirrored by activity of the intracellular signalling pathways governing muscle protein homeostasis. [27] The inability to generate a synthetic response has been identified within muscle as opposed to nutritional delivery.[32] Anabolic resistance (the inability to synthesise protein despite adequate amino acid delivery) results in a drop in myofibrillar synthetic rates by 60%.[32]

Bioenergetic Impairment

MPS is a highly energy-dependent process and its depression may be the result of altered metabolism. Reductions in mitochondrial numbers[33] and function[34-36] have been described, and intramuscular ATP declines during critical illness irrespective of nutritional delivery.[37] This is mirrored by decreases in phosphorylated and total creatine, likely contributed to by the observed myonecrosis (see below). Beta-oxidation additionally declines, rendering fatty acid delivered as part of nutrition or sedation (propofol) relatively inert bioenergetically.[37] Insulin resistance is well described in critical illness, and is in part the result of impaired GLUT-4 translocation, worsening the bioenergetic impairment.[38]

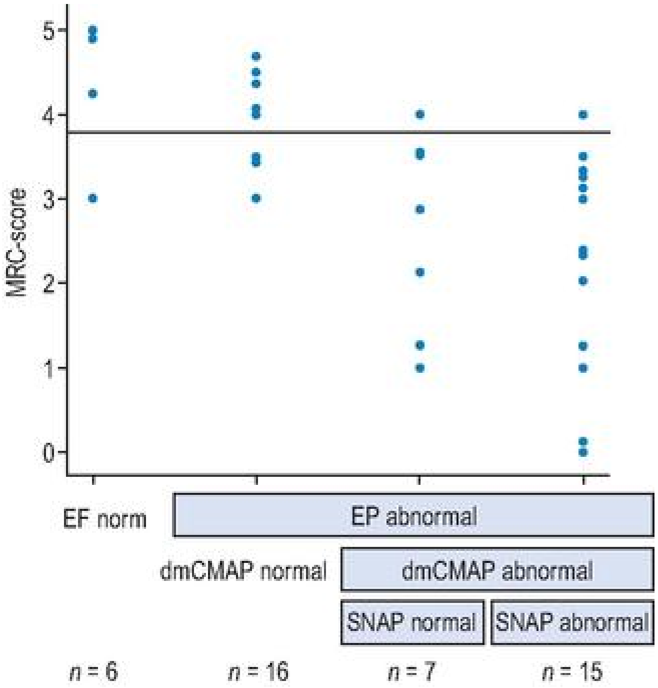
Skeletal Muscle Inflammation

Inflammation is well described as a suppressant of muscle protein synthesis[39] and intramuscular inflammation occurs in critically ill patients related to altered protein homeostasis.[40] Additionally, this may impede recovery from myonecrosis by affecting macrophage function.

Impaired Muscle Membrane Excitability

ICU-AW was originally described as a distal, axonal neuropathy[13] before observational data revealed the far greater prevalence of muscle wasting.[6,27] However, inflammation in experimental settings has been shown to affect muscle membrane excitability.[16] This is likely to be the result of inactivation of the voltage-gated muscle membrane sodium channels.[41] Additionally, sepsis models have suggested altered contractility secondary to deranged intracellular calcium homeostasis.[42]

In critically ill patients, this was elegantly demonstrated to be clinically relevant by the ability of the compound muscle action potential after direct muscle stimulation to be decreased in critical illness and to be highly predictive of subsequent ICU-AW [43] (Fig. 66.5).

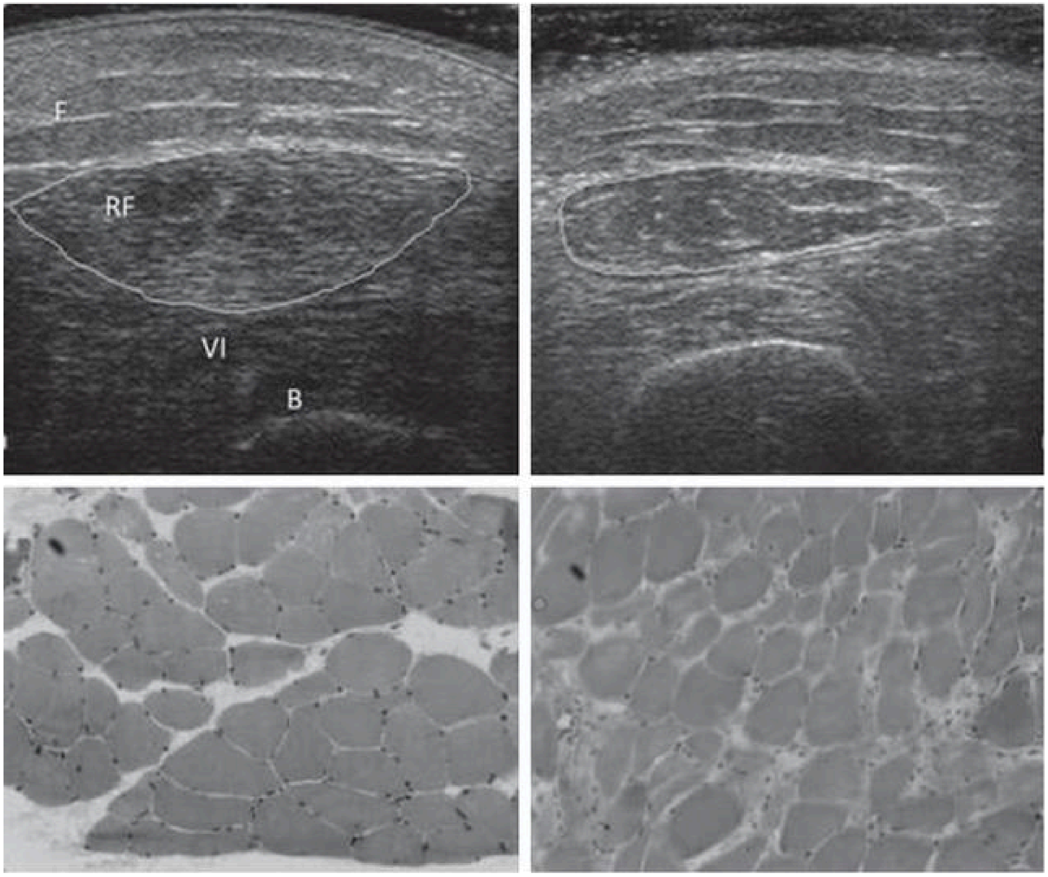


The dot plot displays Medical Research Council scores distributed across four groups defined by combinations of electrophysiological results. The vertical axis ranges from zero to five and represents individual scores. The horizontal axis contains four categories based on normal or abnormal findings in efferent function, compound muscle action potential, and sensory nerve action potential. Each dot represents one patient's score and is placed above the corresponding group. A horizontal reference line appears at score four. The first group includes patients with all normal values and has scores mostly at higher levels. The second and third groups show more variability. The fourth group, with all values abnormal, has multiple low scores. Sample sizes are noted below each category. The layout maintains consistent spacing and labelling.

(From Weber-Carstens S, Koch S, Spuler S, et al. Nonexcitable muscle membrane predicts intensive care unit-acquired paresis in mechanically ventilated, sedated patients. *Crit Care Med* . 2009;37:2632–2637.)

Loss of Muscle Quality

In addition to muscle mass loss, loss of muscle quality is seen. Over 40% of patients develop patchy myonecrosis, detectable non-invasively by muscle ultrasound (Fig. 66.6). This necrosis is accompanied by a macrophagic infiltrate, and a fasciitis. [44] The pathological relevance of the macrophages remains unclear, though their presence may reflect the clearance of dead tissue in preparation for regeneration.



The paired ultrasound and hematoxylin eosin sections depict rectus femoris changes between day one and day ten showing reduction in cross sectional area, increased echogenicity, and presence of myofiber necrosis with cellular infiltrates indicating progressive muscle wasting.

FIG. 66.6 Paired ultrasound and hematoxylin and eosin-stained sections of a patient on day 1 and day 10, demonstrating the reduction in rectus femoris (RF) cross-sectional area, an increase in RF echogenicity and the presence of myofiber necrosis with cellular infiltrate on day 10. *B* , femoral bone; *F* , fascial layer; *VI* , vastus intermedius. (Reproduced from Puthucheary ZA, Phadke R, Rawal J, et al. Qualitative ultrasound in acute critical illness muscle wasting. *Crit Care Med* . 2015;43(8):1603–1611.)

Regeneration may not however be straightforward – a small human study suggests aberrant expression of regenerative genes [45] which may result in a mass/strength mismatch [46] (i.e. larger mass not being associated with greater strength).

Axonal Degeneration

Neuropathies remain poorly understood, given the intrinsic difficulties in tissue analysis. Axonal degeneration may occur secondary to endoneurium microvascular changes, [47] with either neurotoxicity or oedema leading to axonal destruction. [48] Hyperglycaemia may also contribute to axonal damage. [49]

Risk Factors

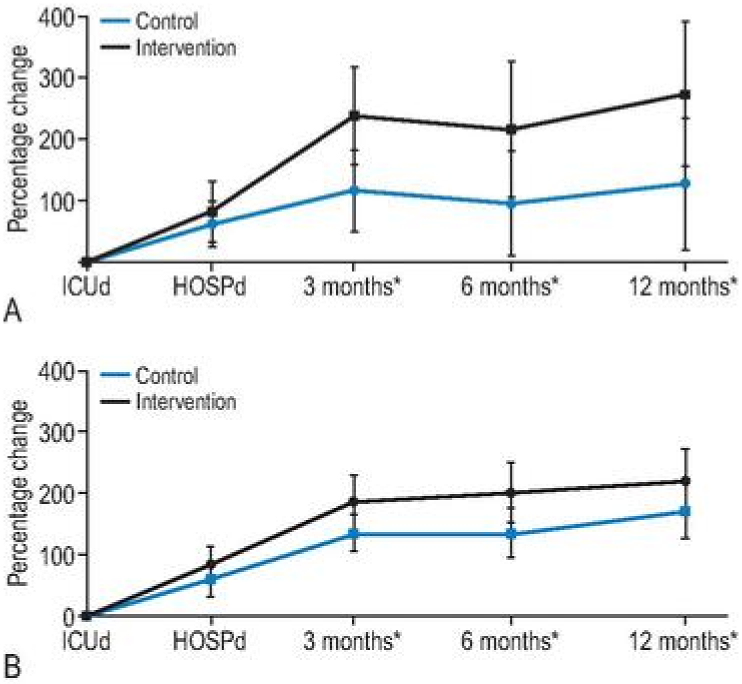
These can be divided into pre-existing and in-ICU risk factors. The pre-existing risk factors of low muscle mass, age and presence of chronic disease have significant overlap, and relative contributions are often hard to dissect, which has led to the translation of the concept of frailty into critical care.

Baseline Muscle Mass

While few studies exist specifically relating baseline muscle mass with subsequent muscle wasting and functional disability, low muscle mass is clearly associated with poor functional status across the spectrum of health and disease. In health, muscle mass is directly related to muscle strength. The loss of further muscle from critical illness can only exacerbate this. Indirect evidence exists within the Nutrition Risk in Critically ill (NUTRIC) score data where a low BMI is a predictor of mortality. [50] Within the critical illness literature, low skeletal muscle mass [51] and quality [52] are predictors of mortality. The diagnosis of ICU-AW is an independent predictor of mortality too, [6], [24] and the combination of these observations allows confidence in the role of low pre-existing muscle mass in subsequent ICU-AW and functional disability.

Pre-Existing Chronic Disease

The presence or absence of chronic disease as a risk factor for ICU-AW is not clear. What is clear is that chronic co-morbidities lead to decreased muscle mass, and decreased function and physical activity post intensive are (compared to those without). A differential response to exercise rehabilitation also exists (Fig. 66.7). Separating the specific contribution of chronic disease states from disuse muscle atrophy is not currently possible. The presence of a chronic disease state should prompt a detailed functional history to be taken.

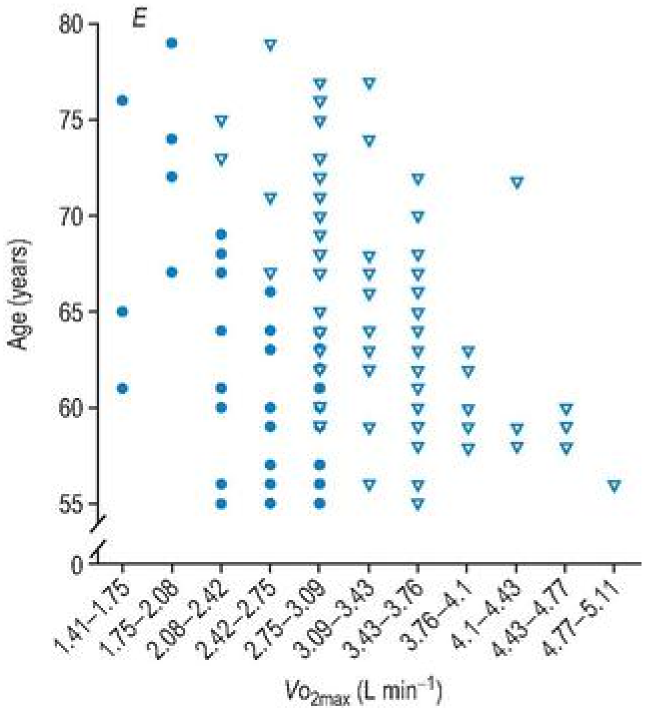


The two line graphs labelled A and B compare control and intervention groups over time. The horizontal axis includes five time points: intensive care unit discharge, hospital discharge, three months, six months, and twelve months. The vertical axis represents percentage change. In graph A, both groups increase in values, with the intervention group consistently above the control group. In graph B, the same trend continues with lower overall change. Error bars extend from each data point. Lines connect values at each time point. The intervention group line is consistently higher.

FIG. 66.7 (A) Change in 6-minute walk test from ICU discharge in patients with no pre-existing chronic disease and (B) those with pre-existing chronic disease. *Broken lines* represent control groups, and *solid lines* those undergoing exercise rehabilitation. *HOSPd* , Hospital discharge; *ICUd* , intensive care discharge. (From Puthucheary ZA, Denehy L. Exercise interventions in critical illness survivors: understanding inclusion and stratification criteria. *Am J Respir Crit Care Med* . 2015;191(12):1464–1467.)

Age

The vast majority of data informing this field is observational, and the effect of age *per se* separated from accompanying chronic diseases and sarcopaenia is difficult to dissect. The use of numerical age alone as a risk factor is controversial but may have a role: anabolic resistance (the inability of muscle protein synthesis in response to resistance exercise and nutrition) is well described in the elderly.[53], [54] However, it may be that high-functioning elderly patients are different – research into master athletes clearly demonstrated the dissociation between numerical age and physiology except at the extremes of age[55] (Fig. 66.8).



The scatter plot displays the relationship between age and peak oxygen uptake across categorised ranges. The vertical axis lists age from 0 to eighty years. The horizontal axis contains ranges of peak oxygen uptake in litres per minute. Data points are represented by two distinct marker types. The first marker type appears across most oxygen uptake ranges. The second type clusters toward the centre range. Distribution patterns show a concentration of data in middle oxygen uptake values. Fewer data points are found at extreme ranges. The vertical spread varies, with broader age distributions in central oxygen categories. The layout is evenly spaced. Each dot marks an individual participant. No connecting lines are present. Both axes include clear labels and divisions.

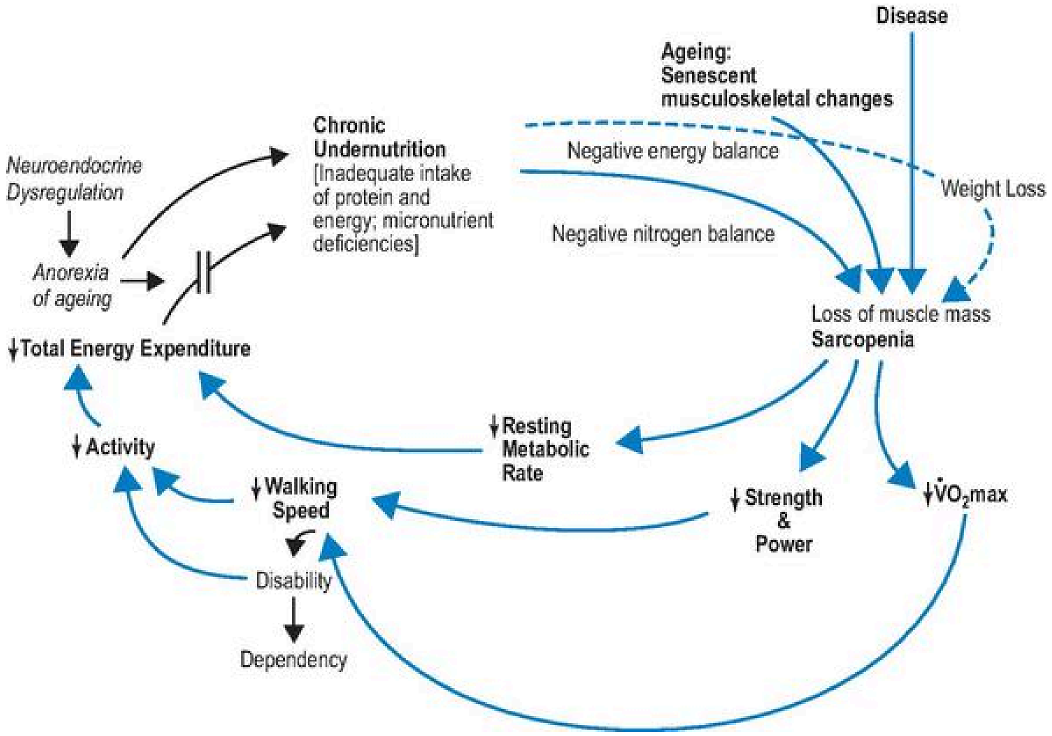
FIG. 66.8 VO$_{2max}$ in healthy master athletes demonstrating poorer than expected correlation between numerical age and cardiopulmonary physiology. (From Lazarus NR, Harridge SD. Declining performance of master athletes: silhouettes of the trajectory of healthy human ageing? *J Physiol*. 2017;595(9):2941–2948.)

There exist several large observational studies suggesting that age does matter. For example contrasting studies of critically ill patients in their 40s [56] and 50s [57] show very different outcome trajectories with the latter having only 9% alive without functional dependence in one study. In an 8-year follow-up study, older patients had a higher rate of new functional limitations compared to younger patients and a higher decrement in function.

Batt et al. [58] summarise this complex issue of baseline health with ' ... *there appears to be a clear prognostic signal in the elderly in terms of the importance of physiological reserve, burden of chronic organ dysfunction, and nature of the health trajectory before the critical illness for prognostication for survival, function, and Health Related Quality of Life. An emphasis on physiological rather than chronologic age and by inference the degree of fitness and muscle reserve may provide valuable insight into projected outcome*'. These interactions hold true in observational studies where age [59] and/or chronic disease [60] were used to stratify functional outcomes.

Frailty

The construct of frailty was first described in the geriatric literature, [61] and is defined as ' *a biologic syndrome of decreased reserve and resistance to stressors, resulting from cumulative declines across multiple physiologic systems, and causing vulnerability to adverse outcomes*' (Fig. 66.9). This is therefore separate from disability and chronic disease, though these conditions, as stated above, overlap considerably.



Disease
Ageing:
Senescent musculoskeletal changes
Chronic Undernutrition
[Inadequate intake of protein and energy; micronutrient deficiencies]
Negative energy balance
Weight Loss
Neuroendocrine Dysregulation
Negative nitrogen balance
Anorexia of ageing
Loss of muscle mass
Sarcopenia
↓Total Energy Expenditure
↓Resting Metabolic Rate
↓Activity
↓Walking Speed
↓Strength & Power
↓V̇O₂max
Disability
Dependency

The flow diagram illustrates interconnected pathways contributing to muscle loss and functional decline. It begins with ageing and neuroendocrine dysregulation leading to decreased appetite and chronic undernutrition. These contribute to lower total energy expenditure. Arrows link to reduced activity, which causes decreased walking speed and increased disability. Further arrows indicate reduced resting metabolic rate and decline in strength and power. The pathway continues to reduced oxygen uptake and loss of muscle mass. Negative energy balance and nitrogen balance also feed into muscle loss. Final outcomes include sarcopenia, disease progression, and dependency. Arrows form loops indicating feedback cycles among multiple factors. All components are clearly labelled and connected using directed lines.

FIG. 66.9 The cycle of frailty. (From Fried LP, Tangen CM, Walston J, et al. Frailty in older adults. *J Gerontol A Biol Sci Med Sci.* 2001;56(3):M146–M157.)

Several forms of assessment for frailty exist. The Clinical Frailty Score has been used repeatedly in observational studies, including critically ill patients, to both assess and grade frailty. It has good construct validity with objective functional measures. [60] The Fried frailty phenotype quantifies deficits in five domains: weakness (measured by hand-grip strength), slowness (measured by gait speed over 15 feet), exhaustion (measured by questions about effort and motivation), shrinking (defined as unintentional weight loss of ≥10 pounds in the last year) and low activity (determined from a validated questionnaire). [62] Each frailty domain is assigned 1 point if present or 0 if absent based on established cutoffs (range, 0–5). Participants have been traditionally classified as robust (0 points), pre-frail (1– 2 points) or frail (≥3 points).

Frail patients are highly likely to have low muscle mass, given that a fundamental of the frailty diagnosis is altered physical function. What is key here is that frailty is a spiral: not only do these patients have low muscle mass, but they are also unable to increase this, with their default being to continue to lose muscle. Hospitalisation with critical illness accelerates the frailty process in adults of all ages. [63]

Illness Severity and Length of Stay

Muscle wasting is related to the severity of illness: Patients with a single-organ failure seem to lose no appreciable muscle in the first 10 days of critical illness, while those with 2–3 organs failing (defined using SOFA scores) lose 20% in the first 10 days on average, and those in 4–6 organ failure lose more, averaging 26% lost in the same time period [27] (Fig. 66.2).

ICU Length of Stay

With muscle wasting occurring at rates of 2%–3% per day, it is perhaps unsurprising that the greater the length of stay, the greater the muscle mass lost. Length of stay is also a risk factor for subsequent functional disability as a result.[59] This was very clearly seen in the COVID-19 pandemic, with profound weakness seen with increased lengths of stay and associated high levels of sedation.[64]

Glycaemic Control

Insulin resistance secondary to impaired glucose transporter (GLUT-4) translocation is well-recognised in critically ill patients.[38] Hyperglycaemia results in mitochondrial damage[65,66] and strict glycaemic control improves mitochondrial function.[67] Insulin itself decreases muscle protein breakdown,[68,69] and separating glucose/insulin interactions is difficult. Regardless, tight glucose control has proven to be hazardous to patients in large pragmatic trials, and is not recommended.[70]

Immobilisation and Sedation

The effects on muscle protein homeostasis and muscle mass of immobilisation have been long established. While bedrest alone results in detectable muscle wasting within 10 days[71] as a result of decreased muscle protein synthesis,[72] immobilisation due to prolonged mechanical ventilation in critical illness may be worse, given the metabolic effects of bedrest – insulin resistance, decreased aerobic capacity and anabolic resistance.[73]

Sedation remains an unquantified risk factor given the dependent relationship with immobilisation. However, duration of mechanical ventilation has been found to be an independent risk factor for ICU-AW.[74] Direct pharmacological effects of propofol and benzodiazepines on post-synaptic skeletal muscle receptors may attenuate neurotrophic stimulation of muscle mass.[73]

Inflammation

Systemic inflammation is a common feature of critical illness. In human endotoxin experiments, inflammation suppresses muscle protein synthesis.[39] C-reactive protein concentrations are associated with loss of muscle mass[27] and intramuscular pro-inflammatory cytokine concentrations are strongly related to impaired anabolic signalling.[40]

Tumour necrosis factor alpha (TNFα) and its superfamily are the most studied of the pro-inflammatory cytokines. High circulating levels and TNF receptor activation promote muscle atrophy via nuclear factor kappa beta (NFκβ) pathways. Additionally, apoptosis may be triggered by TNF receptor activation, leading to decreases in mitochondrial density and therefore energy availability,[40] and potentially necrosis.[44]

Unproven Risk Factors

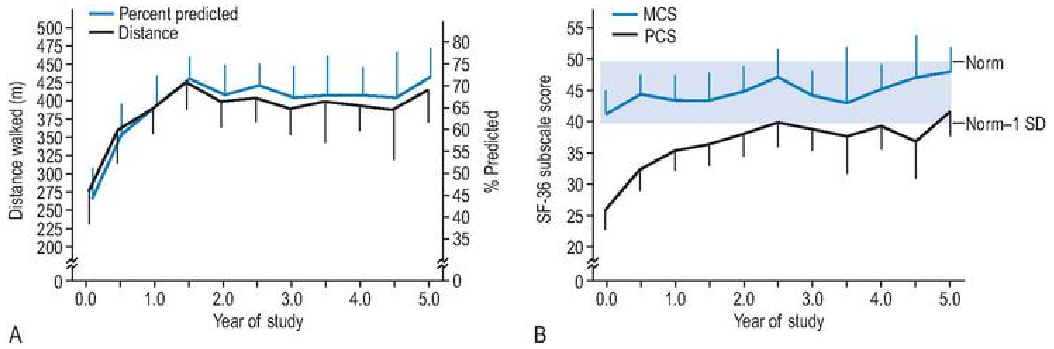
Neuromuscular blocking agents (NMBAs) have repeatedly been examined as a risk factor for ICU-AW.[74] An important distinction is that ICU-AW is not prolonged neuromuscular blockade, which is the result of decreased drug clearance.[75] There is a clear lack of associative evidence,[4,74] and examining the historical context of the association reveals the far greater likelihood that the observed association was the result of concomitant high-dose steroids, use of ventilators without synchronised or spontaneous modes or both.[74,76] In a randomised controlled trial of patients with ARDS, no increase in the incidence of ICU-AW was noted with 48-hour infusions of cis-atracurium,[77] even in the sub-cohort that received corticosteroids.[78] Importantly, there was a reduction in systemic inflammation . In another randomised controlled trial of patients with moderate-to-severe ARDS, a 48-hour infusion of cisatracurium with concomitant deep sedation compared to usual care with lighter sedation targets found no difference in the rates of ICU-acquired weakness between the groups. Many patients (range, 51.2%–67.5%) could not complete the weekly in-hospital assessments of muscle strength, which is a common limitation of assessment of muscle strength in ICU with volitional tests.[79]

Clinical Relevance

Survival and functional disability are rarely discussed acutely on admission to intensive care. However, this is of increasing relevance to patients and families, in the face of a significant year-on-year decrease in mortality worldwide. Survival is not without cost.[80,81] The facts surrounding survival need to be clearly communicated to patients and families: muscle wasting occurs at rates of 2%–3% per day,[27] and a 10% loss of muscle mass is considered sufficient to affect physical function.[26] Some patients may never fully recover. This is likely to affect patient and families in four domains:

Long-Term Functional Disability

Herridge's landmark observational study in 2003[56] demonstrated the significant functional disability observed in survivors and these findings of ongoing disability have been confirmed repeatedly.[80,81] We now know that although 75% of patients are discharged,[82] long-term impairment of physical function and quality of life are common: substantial functional limitations occur in 70% at 6–12 months, and 30% are carer-dependent.[56,83] Approximately one-third of working-age patients never work again.[56,84] Patients,[85] the National Institute of Clinical Excellence (UK)[82] and researchers[56] recognise muscle wasting and weakness as a major contributor to this functional deficit which may persist for up to 5 years[86] (Fig. 66.10) and in the setting of older age and co-morbidities, worsen[87] over time.



The two line graphs are labelled A and B. Both have the same horizontal axis representing years of study from zero to five. Graph A displays distance walked and percent predicted values on the vertical axis. Two lines track these values over time. Graph B presents health survey scores for physical and mental components. A shaded band marks the range between the norm and one standard deviation below the norm. The mental component line remains higher than the physical component line. Error bars extend from each point in both graphs. Graph A shows an initial rise in both values, followed by levelling off. Graph B shows a gradual upward trend. Each graph includes axis labels, legends, and consistent spacing.

FIG. 66.10 Trajectories of recovery from critical illness over 5 years. *MCS* , Mental component score; *PCS* , physical component score; *SF-36* , short form 36. (From Herridge MS, Tansey CM, Matté A, et al. Functional disability 5 years after acute respiratory distress syndrome. *New Engl J Med* . 2011;364(14):1293–1304.)

Discharge Planning

Functional disability is now accepted as a major consequence of ICU-AW,[88] and often compounded by cognitive impairment [89] which may recover eventually. [86] Critically ill patients lose muscle mass rapidly, and prolonged stays may result in discharges to intermediate care centres as opposed to home. [90] The elderly and those with pre-existing co-morbidity are often less likely to return home. Discharge destination can be predicted by measures of mobilisation such as the ICU Mobility Scale (IMS) [91], [92] and functional outcome assessment such as the Chelsea Critical Care Physical Assessment Tool, [93] which are well used internationally. [94] The IMS is an 11-point scale that ranges from 0 to10 (0=no exercises, or passive exercises in bed to 10=walking independently without a gait aid or assistance). It is used in international registries and trials to measure the level of mobilisation in the ICU. Clinimetric testing of the IMS has demonstrated a difference in values for patients with and without ICU-acquired weakness. In addition, increasing IMS values at ICU discharge were associated with survival to 90 days (odds ratio [OR], 1.38; 95% confidence interval [CI], 1.14–1.66) and discharge home (OR, 1.16; 95% CI, 1.02–1.32). [91] Interestingly (likely due to the contribution from pre-illness muscle mass and co-morbidities) discharge destination can be predicted very early in the course of critical illness [59], [95] and the likely destination should be communicated early.

Length of Stay and Ventilation

Observational studies have repeatedly demonstrated the association between muscle weakness and increased ICU length of stay, using various methods such as muscle ultrasound, [27] hand-grip strength [24] and the MRC-Sum Score. [6] The effect on ventilator dependence has also been demonstrated, with one study seeing 9 days on average longer duration of ventilation, specifically post awakening, [96] which has significant implications for the planning of tracheostomy and avoidance of risk factors for ICU-AW related to longer ICU stay. A recent systematic review found the risk factors for ICU-AW include delirium, infections, renal replacement therapy and hyperglycaemia. [74]

Long-Term Mortality

Short-term mortality rates from critical illness continue to fall. However late mortality [57], [97-106] remains high: 5-year mortality was 61% amongst 439 survivors of severe sepsis [107] and 58% amongst 300 mixed ICU survivors, [99] data similar to those reported by others. [86], [108-111] In studies with careful matching and control for confounding, pneumonia, [7] sepsis [8] and all-cause critical illness [9] have each been found to increase survivor's risk for late mortality, independent of age and baseline health status. Overall, increased risk of death over 5 years (relative risk 3.4 when compared to the general population [111]) may extend to 15 years or more after discharge. [109] Death from the diseases that led to ICU admission [112-114] or from significant chronic disease predating ICU admission [115], [116] tend to occur in the first 6–12 months. Thereafter, for reasons, which are unexplained, malignancy and chronic cardiovascular diseases dominate as causes of death. [112-114] In a study of 156 ARDS survivors [117] muscle weakness at hospital discharge was independently associated with 5-year mortality regardless of trajectory of recovery (i.e. those with persistent weakness had the same mortality as those with resolving weakness). Swallowing dysfunction, [19] decreased nutritional intake, [19] increased aspiration [19] and decreased physical activity [20] are all sequelae of muscle weakness. Decreased physical activity may in turn increase the risk for cardiovascular events and malignancy. Individually or in combination these factors may impair muscle protein synthesis, leading to a vicious cycle of maintained cachexia and increasing mortality. [21]

With these consequences of surviving critical illness in mind, clinicians need to ascertain physiological reserve, burden of chronic organ dysfunction and nature of the health trajectory before the critical illness for prognostication for survival, function and health-related quality of life. These facts need to be communicated to families and whenever possible, the patient.

Prevention and Treatment

Nutrition: As a result of our incomplete understanding of the pathophysiology of ICU-AW, to date, trials of additional substrate delivery [118-124] have yet to preserve muscle mass and improve outcomes. Specifically, the TARGET and EFFORT trials have failed to identify improvements in patient outcomes from increased nutritional delivery. [125], [126]

Altered substrate utilisation from hypoxia and inflammation prevents carbohydrates and fatty acids from being used for ATP generation. [37] A lack of energy for protein synthesis leads to excess protein being diverted to ureagenesis, and potential excess ammonia. [127], [128] Intermittent feeding to overcome the muscle full effect did not maintain muscle mass, despite altering protein metabolism. [129], [130]

Glucose control : In a meta-analysis of two large randomised controlled trials of tight glucose control, intensive insulin therapy resulted in a decrease in electrophysiological abnormalities in patients ventilated >1 week. [131] However, the impracticalities of such treatment were demonstrated in the NICE-SUGAR trial where an unacceptable incidence of hypoglycaemia and mortality was noted. [132] Current best practice is to avoid hyperglycaemia.

Neuromuscular electrical stimulation: Multiple trials in the acute setting have failed to demonstrate a benefit on muscle mass. [133-137] Statistically positive trials exist with methodological issues related to mass measurement techniques, which have not been reproduced by the same investigators.

Physiologically, electrical stimulation is unlikely to have a beneficial effect in the acute setting, in the presence of an impaired anabolic response. [27] Further, resistance exercise is needed for an anabolic stimulus, as opposed to simple muscle contraction. Lastly, non-excitability is predictive of ICU-AW, and by definition, is unaffected by electrical stimulation. [43] There is a high chance for harm – muscle necrosis is common [44] (Fig. 66.6) and electrical stimulation results in direct muscle damage. [138] Trials of functional electrical stimulation have further failed to result in muscle mass maintenance. [139], [140]

ABCDEF: Preventing muscle wasting and subsequent functional disability are intertwined goals. It is unlikely that a single intervention will manage this. The ABCDEF [141] bundle represents the best intervention available, and has been demonstrated to additionally decrease mortality significantly in a cost-neutral fashion. [142], [143] The bundle components are:

ABBREVIATION	**INTERVENTION**
A	Awakening trials [144]
B	Spontaneous breathing [145]
C	Co-ordination of care [145]
D	Delirium assessment
E	Early mobilisation [146]
F	Family engagement

Technically the evidence for each of these is related to mortality or ICU/hospital length of stay rather than treating ICU-AW *per se* . However, the evidence includes or requires increases in physical functioning, which, all things being equal, can only be achieved by addressing muscle mass and function. Early mobilisation requires volitional muscle contraction to participate in rehabilitation and therefore it cannot occur without other aspects of the bundle.

Early mobilisation : The prevalence of ICU-acquired weakness at ICU discharge within randomised controlled trials of early rehabilitation versus standard care is shown in Fig. 66.11 . This analysis included over 1000 randomised critically ill patients. Although the effect favours early mobilisation, the pooled estimate is not significant. A phase III trial in 750 mechanically ventilated patients across 6 countries (the TEAM trial) tested an intervention which included the highest level of rehabilitation and mobilisation possible compared to usual care rehabilitation and mobilisation. The intervention included interdisciplinary discussion to coordinate care, safety checklists and sedation minimisation. The authors found no difference in the primary outcome, days alive and out of hospital to day 180. However, they found a signal for harm in the intervention group due to an increase in adverse events, including altered blood pressure, cardiac arrhythmia and oxygen desaturation. While it is important to consider rehabilitation and mobilisation early in critically ill patients to maintain muscle strength and function, the optimal dose and timing of rehabilitation are unknown and caution should be taken to monitor for adverse events.

	Intervention		Control			Risk ratio
Study or Subgroup	Events	Total	Events	Total	Weight	M-H, Random, 95% CI
Zhu 2018	1	20	8	20	1.8%	0.13 [0.02 , 0.91]

Total events:	181		211			

Heterogeneity: Tau² = 0.12; Chi² = 26.34, df = 10 (P = 0.003); I² = 62%
Test for overall effect: Z = 1.55 (P = 0.12)
Test for subgroup differences: Not applicable

The forest plot presents a meta-analysis seta analysis comparing risk ratios from multiple studies. Each study is listed in rows with details including intervention events, total participants, control events, and weight. Horizontal lines extend across a central axis to represent confidence symbols. A diamond at the bottom summarizes the overall effect size with its confidence interval. A vertical line at value one represents no effect. Risk ratios are plotted as squares along the line, with square size reflecting study weight. Soo-effect me intervals cross the no effect line. Columns include numerical values for risk ratio and confidence interval. The bottom section includes total events, heterogeneity values, and statistical significance indicators. Labels are aligned in columns.

FIG. 66.11 Forest plot of the prevalence of ICU-acquired weakness at ICU discharge with randomised controlled trials of early mobilisation versus standard care. (From the Australian NHMRC guidelines for the rehabilitation and mobilisation of critically ill patients, https://www.monash.edu/medicine/intensive-care-cre/development-of-an-australian-clinical-guideline-for-physical-rehabilitation-and-mobilisation-in-adult-intensive-care-units).

Despite the neutral cost and significant patient and institutional gains from bundle implementation, the ABCDEF bundle has yet to become a standard of care, as a result of workplace cultural issues centred on de-sedation, early mobilisation and co-ordination of care.[147, 148]

Post-Discharge Management

Rehabilitation: As yet no evidence exists that post-discharge rehabilitation leads to increases in physical function or quality of life in critical care survivors, despite a number of high-quality multi-centre randomised controlled trials.[149-155] This may be a result of trial methodology[156] and/or a failure to account for baseline function[60] (Fig. 66.7). Nevertheless, physical and exercise rehabilitation remains a recommendation in survivors.[82]

Bone health : Survivors of critical illness have an increased fracture risk.[157, 158] This is the result of a combination of pre-existing osteopaenia, and the acute effects of critical illness on bone mineral density and structure.[159] In the setting of low muscle mass and decreased mobility, these patients represent a high falls and fracture risk. A comprehensive falls assessment is needed, as is staging of osteopaenia.

Nutrition: Ingestion of protein is mandatory for muscle protein synthesis to occur, preferably following resistance exercise. There is some evidence of poor appetite among critical illness survivors. This coupled with functional disability that may limit activities of daily living, including shopping and cooking, financial constraints following loss of income and hospital costs may lead to poor dietary habits and into the spiral of continued muscle wasting and functional decline.

Small fibre neuropathy: Two studies have described loss of small fibres, resulting in neuropathic pain and non-dermatomal sensory loss.[160, 161] These symptoms may be difficult to control, and if non-responsive to first-line neuropathic pain treatments (e.g. gabapentin or amitriptyline) expert advice should be sought and formal diagnosis criteria checked.[162]

Nerve entrapment: Focal compression neuropathies with normal electro-diagnostic testing may occur.[163] In a 1-year follow-up series, this was noted in 7% of patients.[56] While foot drop (a common compression neuropathy) is often recognised and treated by physiotherapists, uncommon compression neuropathies may need specialist neurological diagnostic input.

Patients, families and healthcare professionals need to be made aware of the sequelae of surviving critical illness rather than a pure focus on immediate mortality. Multidisciplinary healthcare workers outside the ICU, including primary health practitioners, need to be made aware of ICU-AW and the long-term consequences on functional recovery. This may have profound ramifications for their own discussions with patients regarding subsequent/ongoing treatment of complex conditions such as neoplastic disease (chemotherapy having a pre-requisite of good performance status) and complex surgery (recovery of muscle mass and rehabilitation not occurring in the short term). Only in this fashion can patients and families weigh the cost/benefit ratio of intensive care treatment versus subsequent quality of life.

Neuromuscular disorders

Manoj Krishan Saxena and Walid Matar

Guillain–Barré Syndrome

Guillain–Barré syndrome (GBS) is a rapidly progressive, monophasic, immune-mediated polyneuropathy. Acute immune-mediated polyneuropathies are classified under the eponym ‘Guillain–Barré’, although the first case description was reported in 1834 by James Wardrop.[1], [2] The disease affects the peripheral nerve roots, myelin and axonal components of mainly motor nerves; sensory fibres, cranial and sympathetic nerves are also often affected. Two major variants are now recognised and referred to as acute inflammatory demyelinating polyradiculoneuropathy (AIDP) or acute motor axonal neuropathy (AMAN), with acute motor and sensory axonal neuropathy (AMSAN) being a variant of the latter.[3–5]

Incidence

Since the incidence of poliomyelitis has markedly declined due to mass immunisation programmes, GBS has become the major cause of rapid-onset flaccid paralysis in previously healthy people, with an incidence of approximately 1.7 per 100,000.[6] The disorder is commoner in males, and up to four times commoner in the elderly. No consistent seasonal or racial predilection has been demonstrated.

Aetiology

Most recent evidence supports the proposition that the AMAN and AMSAN variants of GBS are antibody-mediated nerve injuries. [5], [7], [8] This process may be driven by accidental molecular mimicry between surface gangliosides [9], [10] on the nerve and an antecedent microbial antigen, such as *Campylobacter jejuni* . [11], [12] However, it is important to note that unwanted autoimmunity does not arise in most individuals exposed to *C. jejuni* infection. [13]

The immune mechanism underlying AIDP is less well elucidated, and this may be because of a greater heterogeneity in antecedent microbial infections or immune stimulation.

An emerging entity is GBS associated with the use of immune checkpoint inhibitors which are increasingly being used in oncology. [14]

Three-quarters of cases are preceded by symptoms suggestive of respiratory or gastrointestinal infection. Other antecedent events include trauma, vaccination, blood transfusion, chemotherapy, or surgery. *C. jejuni* gastroenteritis now appears to be the most common predisposing infection and may be associated with a more severe clinical course. Cytomegalovirus infection accounts for a further proportion of cases. [15] Other infective agents implicated include influenza A, hepatitis E, [16] parainfluenza, *haemophilus* , [17] varicella-zoster, Epstein–Barr, chickenpox, mumps, human immunodeficiency virus, [18] measles virus, *Mycoplasma* , Zika virus and severe acute respiratory coronavirus 2 (SARS-CoV-2) .

Immunisations against viral infections, tuberculosis, tetanus and typhoid have all been reported to be associated with the onset of GBS, but most of these reports are anecdotal and of questionable aetiological significance. [19] Surveillance data following the 2009 H1N1 influenza epidemic suggested that the risk of GBS following immunisation was only marginally increased over baseline [20] ; and this finding has been confirmed by a large Chinese case-control study. [21] The prevalence of GBS after vaccination against SARS-CoV-2 may be marginally increased over the background population rate of the disease. [22]

Pathogenesis

The AIDP variant is macrophage-mediated and the lesion is primarily demyelination with some secondary axonal injury. These forms are associated with the GM-1 antibody in 7%–35%.

The AMAN and AMSAN variants are primarily an axonal lesion that is antibody and membrane attack complex-mediated, affecting the nodes of Ranvier with minimal demyelination evident. GM-1 (50%–60%), GD1a and GA1NAc-GD1A antibodies are associated.

Clinical Presentation

Most patients describe a minor illness in the 6 weeks prior to presentation, with a peak incidence 2 weeks beforehand. Patients typically present with sensory symptoms and lower motor neuron weakness with hypotonia and reduced or absent reflexes in the lower limbs that progress to the upper limbs and cranial nerves, although the clinical presentation is heterogeneous and a number of distinct clinical patterns exist.[23] GBS can also present atypically; weakness and sensory signs can be asymmetrical or predominantly proximal or distal and can start in the lower limbs, the upper limbs, or in all limbs simultaneously. Furthermore, severe and diffuse pain or isolated cranial nerve dysfunction can precede the onset of limb weakness (Box 67.1).

Box 67.1

Diagnostic criteria for typical Guillain–Barré syndrome

Features required for diagnosis

Progressive weakness in both arms and both legs
Areflexia

Features strongly supportive of the diagnosis

Progression over days to 4 weeks
Relative symmetry of symptoms

Mild sensory symptoms or signs
Cranial nerve involvement, especially bilateral weakness of facial muscles
Recovery beginning 2–4 weeks after progression ceases
Autonomic dysfunction
Pain
High concentration of protein in cerebrospinal fluid protein, with fewer than 10×10^6 cells/L
Typical electrodiagnostic features

Features that should raise doubt about the diagnosis of Guillain–Barré syndrome

Mononuclear cell count in CSF >50 cells per µL
Presence of fever at onset
Severe pulmonary pathology with minimal limb weakness at onset
Persistent bladder or bowel dysfunction
Sharp spinal cord sensory level
Persistent asymmetry of weakness
Slow progression of weakness without respiratory involvement
Purely sensory syndrome, without weakness

Maximum weakness may take 4 weeks, but most patients have already reached their peak weakness within 2 weeks. Approximately 20% to 30% of patients admitted with GBS will develop respiratory muscle weakness requiring ventilation.

Pain, which can be severe, is frequently reported and can be muscular, radicular or neuropathic.

Cranial nerves are involved in 50% of cases, most commonly the facial nerve, followed by the glossopharyngeal and vagus nerves.

Autonomic dysfunction is a major contributor to morbidity and mortality in ventilator-dependent cases. Autonomic dysfunction is seen in approximately one-third of patients admitted for GBS and it is more common in those with greater weakness. [24] The most common signs of autonomic dysfunction are ileus, blood pressure fluctuations (including orthostatic or persistent hypotension and paroxysmal hypertension), arrhythmias and urinary retention. In-hospital mortality is greater and functional outcomes at hospital discharge poorer in patients with autonomic instability.

In the Miller–Fisher syndrome, cranial nerve abnormalities predominate, with ataxia, areflexia and ophthalmoplegia as the main features.[25] This is strongly associated with recent *C. jejuni* infection and with the presence of GQ1b antibodies.

The triad of ataxia, impaired consciousness, hypersomnolence and symmetrical ophthalmoplegia, with largely preserved limb function is described in Bickerstaff's brainstem encephalitis. Reflexes may be preserved or brisk.[26]

Treatment-related fluctuations occur in up to one-sixth of patients receiving treatment and are thought to be due to persistent immunopathogenic processes that have been transiently arrested by therapy ('pseudo-nadir').[27] This phenomenon is distinct from the acute onset of chronic inflammatory demyelinating polyneuropathy in which patients may have three or more relapses with one or more occurring after 8 weeks of acute onset.

Differential Diagnosis

At the time of referral to intensive care, the diagnosis has usually been made. Important differential diagnoses and distinguishing clinical features are presented in Box 67.2 ; the differential diagnosis includes other conditions with reduced tone, weakness and reduced or absent reflexes. Acute myopathies (myalgia, drug history and elevated creatine kinase), *myasthaenia gravis* (MG) (fatiguable weakness affecting ocular and bulbar muscles), as well as snakebite (fang bite, hypotension/shock and coagulation defects), Botulism, organophosphate poisoning and toxin ingestion, should all be considered.

Box 67.2

Differential diagnosis of muscle weakness in critically ill patients

Location	**Pathology**	**Clinical features**
Brainstem		
	Lower pontine haemorrhage/infarction	Altered conscious level Cranial nerve lesions Upper motor neuron signs in limbs
	Meningitis/encephalitis	Altered conscious level Cranial nerve lesions Upper motor neuron signs in limbs
Spinal cord		
	Compression (e.g. cervical myelopathy or infiltration with tumour, abscess and haemorrhage)	Sensory signs Upper motor neuron signs below level
	Transverse myelitis	Sensory signs Upper motor neuron signs below level
Peripheral nerve		
	Critical illness	Context of sepsis and multiorgan failure Prolonged sedative/anxiolytic effect
	Chronic inflammatory demyelinating	Absence of antecedent infection, insidious onset,

Location	Pathology	Clinical features
	polyneuropathy	gradual worsening, relapses
	Toxins (arsenic, thallium and cyanide)	Arsenic: chronic exposure associated with peripheral sensory/motor neuropathy Thallium: acute gastrointestinal and neurological presentation followed by delayed polyneuropathy, cutaneous and chronic gastrointestinal features Cyanide: Cardiorespiratory dysfunction with altered conscious level and seizures
	Lymphoma, paraneoplastic disease, sarcoidosis	Additional diverse manifestations of the primary disease
Neuromuscular junction		
	Myasthaenia gravis	Fatigable weakness affecting ocular and bulbar muscles
	Pesticide (organophosphate poisoning)	Cholinergic stimulation and lower motor neuron weakness with fasciculations

Location	Pathology	Clinical features
	Botulism	Prominent anticholinergic stimulation (gastrointestinal and ocular) followed by descending paralysis Toxin in stool or urine
	Snakebite	Presence of fang marks; cardiovascular and coagulation defects in addition to neurological features (skeletal and respiratory muscle weakness)
Skeletal muscle		
	Acute myopathies (immune mediated, polymyositis/dermatomyositis, steroids, alcohol, statins, amiodarone, colchicine, bumetanide and cocaine)	Elevated creatinine kinase
	Critical illness	Context of sepsis and multiorgan failure Prolonged sedative/anxiolytic effect

Investigations

In over 90% of patients, CSF protein is increased (greater than 0.4 g/L) within 2 weeks of onset of symptoms. CSF tests can be normal at onset. The CSF protein level does not correlate with the clinical findings. CSF oligoclonal bands are negative. The CSF cell count is typically normal, although a pleocytosis with lymphocytes and monocytes in the CSF may be seen in a small proportion of patients (<15%), especially later in the disease.

Nerve conduction studies may be normal early in the disease and are most useful around 2 weeks after the onset of weakness. Nerve conduction studies can help differentiate between the demyelinating (AIDP) and poorer prognosis axonal (AMAN and AMSAN) subtypes.

In AIDP, nerve conduction studies demonstrate demyelination which includes slowing of motor nerve conduction velocity with prolonged distal motor latency, increased F-wave latency, multifocal conduction block and abnormal temporal dispersion of compound muscle action potential.

In AMAN/AMSAN the hallmark is severely reduced amplitude or absent motor and/or sensory response with relatively preserved conduction velocity and the absence of features of demyelination.

T1-weighted magnetic resonance imaging (MRI) with contrast medium of the cervical or lumbar spine can show thickening and enhancement of nerve roots or the cauda equine. T1-weighted MRI of the brain can show thickening or enhancement of cranial nerve roots. In the case of brainstem involvement, T1-weighted MRI can show hyperintensity of the pons and bulb.

Ganglioside antibodies are directed against sialic-acid-containing glycolipids that are predominantly located at the nodes of Ranvier and at nerve terminals. GM1-antibodies are generally elevated in 50%–60% of AMAN cases but only in 7%–35% of AIDP cases. GQ1b antibodies are elevated in 100% of Miller-Fischer syndrome and Bickerstaff's brainstem encephalitis.

Management

Although the management of patient with severe and protracted GBS provides a major challenge, the prognosis is generally good if complications can be treated early or avoided.

Specific Therapy

Intravenous immunoglobulin (2 g/kg over 5 days) is considered now to be the first line of therapy administered to patients with GBS unable to walk 10 metres. It is preferred to plasma exchange as it is less invasive, has a better side effect profile and has equivalence in efficacy.

Plasma exchange (plasmapheresis) was the first treatment of proven value in GBS with two trials demonstrating a reduction in patients requiring mechanical ventilation; a reduced duration of mechanical ventilation for those who required it; a reduced time to motor recovery; and reduced time to walking without assistance.[28,29] Mortality, however, was not altered. Plasma exchange was most effective when carried out within 7 days of onset of symptoms. The currently recommended plasma exchange schedules consist of four exchanges of 1–2 plasma volumes each, over 1–2 weeks.[30] Adverse events are common.[31]

Immunoglobulin therapy was subsequently demonstrated to be as effective as plasmapheresis.[32] Its ease of use has led many authorities now to advocate immunoglobulin as the treatment of choice[33]; a total dose of 2 g/kg body weight intravenously, over 5 days, is reasonable.[34]

A second or prolonged course of immunoglobulin therapy for patients with a minimal response to a first course of immunoglobulin does not provide benefit and is associated with an increased risk of adverse events including infection and thrombosis.[35]

About 10% of patients relapse after initial treatment (treatment-related fluctuations) with either plasmapheresis or immunoglobulin. There appears to be no benefit in combining plasmapheresis and immunoglobulin treatments, or in crossing over from one to the other.[32]

Low or high-dose corticosteroids are of no value, and may even slow recovery or be associated with harm.[36]

Supportive Care

Respiratory

In the spontaneously breathing patient, chest physiotherapy and careful monitoring of respiratory function are of paramount importance. Regular measurement of vital capacity is probably the best way to predict respiratory failure and is more reliable than arterial blood gases.[37] Any patient with an inability to lift arms above shoulders, with a vital capacity less than 15–20 mL/kg or 30% of the predicted level, an inability to count to 15 in a single breath, or a rising arterial $PaCO_2$ (a late sign of respiratory failure) is likely to require mechanical ventilation.

Bulbar involvement should be carefully sought, as there is a significant risk of aspiration of upper airway secretions, gastric contents or ingested food. The cough reflex may be inadequate, and airway protection by tracheal intubation or tracheostomy is then required. Oral feeding should be stopped in any patient in whom bulbar involvement is suspected.

Mechanical ventilation, necessary in 20%–30% of hospitalised patients, will probably be required for several weeks (although there is wide variation), and early tracheostomy should be considered.

Cardiovascular

Cardiac rhythm and blood pressure should be monitored. Sinus tachycardia is the commonest autonomic manifestation of GBS and usually requires no active treatment. Induction of anaesthesia appears particularly likely to induce serious arrhythmias. Use of suxamethonium may contribute significantly to this and, as with many other neuromuscular disorders, should be avoided.[38] Endotracheal suctioning has also been associated with serious arrhythmias. Cardiovascular instability may also be exacerbated by several drugs (Box 67.3). These, likewise, should be avoided or used with great care.

Box 67.3

Drugs associated with cardiovascular instability in Guillain–Barré syndrome

Exaggerated hypotensive response

Phentolamine
Nitroglycerin

Thiopentone
Morphine
Furosemide

Exaggerated hypertensive response

Phenylephrine
Ephedrine
Dopamine
Isoprenaline

Arrhythmias

Suxamethonium

Mild hypotension and bradycardia may require no treatment, particularly if renal and cerebral functions are maintained. However, blood volume expansion or inotropic drugs may be required in some cases. Hypertension is often transient but occasionally requires drug therapy. Hypoxia, hypercarbia, pain and visceral distension should be excluded as causes.

Fluids, Electrolytes and Nutrition

Paralytic ileus is not uncommon, especially immediately following the institution of mechanical ventilation, and a period of parenteral nutrition may be required. However, nasoenteric feeding is the preferred initial route for feeding.

Sedation and Analgesia

In non-ventilated patients, sedation should be avoided because of the potential for worsening respiratory and upper airway function. In ventilated patients, sedation becomes less necessary as the patient becomes accustomed to the ventilator, but night sedation may help to preserve diurnal rhythms. Limb pain, particularly with passive movement, is very common and often quite severe. Quinine, non-steroidal analgesics and antidepressant drugs may all be tried, but the pain can be difficult to control and opioids are often required. Methadone, transdermal fentanyl, gabapentin and tramadol have all been advocated. The anticonvulsants gabapentin or carbamazepine are useful for neuropathic pain during the acute phase; [39] tricyclic antidepressants may be beneficial for dysaesthetic-type pains.

General and Nursing Care

A comprehensive programme of physiotherapy should be implemented, with careful attention to pressure area care, and the maintenance of joint mobility and pulmonary function. Nosocomial infection should be actively sought. Sites of vascular access should be inspected frequently, and devices changed whenever necessary. It may be possible to manage stable long-term patients without venous access. Care should be taken to prevent corneal ulceration and faecal impaction.

Prophylaxis against venous thromboembolism should be given.

Pain, hallucinations, anxiety and depression are frequent in patients with GBS, and these symptoms should be actively sought, especially in patients with limited communication abilities and/or who are in the ICU. Addressing psychological symptoms and pain at an early stage is crucial as these symptoms can have a major impact on the wellbeing of patients. Non-pharmacologic pain relief therapies include frequent passive limb movements, gentle massage and frequent position changes.

Psychological problems, especially depression, are common. Good communication and rapport between the patient and staff, involvement of allied health practitioners, the provision of television, radio and communication aids and, where possible, occasional trips out of the ICU often have great value.

Prognosis

The clinical presentation and course of GBS are highly variable. Mortality rates in GBS range between 1% and 13% (up to 20% in patients requiring mechanical ventilation). The most common causes of death in patients with GBS relate to respiratory and cardiovascular/autonomic complications. Of those who survive the acute illness, 70% have recovered to functional independence within 1 year, and a further 20% are left with minor limitations.

Neuroprognostication in GBS can be aided by considering prognostic patient factors [40] and the use of predictive algorithms. Poor prognostic features include age over 60 years, a preceding diarrhoeal illness, bulbar involvement, severe motor weakness and rapid progression to quadriparesis in less than 7 days. The need for mechanical ventilation (except for children) and for prolonged mechanical ventilation (>2 months) also predict poorer outcomes. [41] The modified Erasmus GBS outcome score provides a likelihood of walking independently at 4 weeks, 3 months and 6 months. [42] Severely affected patients require a protracted period of rehabilitation. A substantial proportion of patients have residual pain and fatigue that may be attributed to persistent axonal loss. Many patients adapt their work or daily activities even after substantial recovery.

Myasthaenia Gravis

Myasthaenia gravis is a rare, acquired autoimmune disorder of the neuromuscular junction (NMJ), caused by antibodies that target the post-synaptic membrane. The antibodies cause fatigable weakness of skeletal muscles, which is the sole clinical manifestation. Approximately 80% of patients have antibodies (mainly IgG1 and IgG3 subclasses) against the nicotinic acetylcholine receptor (AChR), 5% have IgG4 antibodies against the muscle-specific tyrosine kinase (MuSK), and the remaining 15% are seronegative for both autoantibodies. [43] In the seronegative group of patients, antibodies targeting lipoprotein receptor-related protein 4 (LRP4) and Contactin have been described. [44] In seronegative MG, confirmation of the clinical diagnosis relies on abnormal electrodiagnostic testing.

Despite its relative rarity, it is the most studied and best-understood clinical disorder of neuroreceptor function, and arguably the best-understood organ-specific autoimmune disease. It is characterised clinically by ocular and skeletal muscle weakness and fatigability (muscle weakness that worsens with exercise).

Intensive care is mostly required because of severe involvement of the bulbar or respiratory muscles, which may be the result of a spontaneous exacerbation of the disease, a complication of drug therapy (see Box 67.4),[45] intercurrent illness or surgery or following surgical thymectomy, a component of treatment for some patients.

Box 67.4

Pethidine

Other

Magnesium

The diagnosis of MG is based on the combination of symptoms, signs, electrophysiology and in the majority, a positive test for specific autoantibodies.

Incidence

The incidence of MG is approximately 8–10 per million. There is no racial or geographic predilection. Although MG can occur at any age, it is very rare in the first 2 years of life, and the peak incidence is in young adult females with a smaller, second incidence peak in elderly males. Overall, females are affected about twice as often as males but this gender predilection decreases with increasing age.

Aetiology and Pathophysiology

In 70% of cases, there is histological evidence of thymus abnormalities such as thymoma or hyperplasia, while others have normal or atrophic thymus. [46] Thymus hyperplasia is more common in early onset (<50 years old) disease, whereas approximately 10% have a thymoma and this is more common in the older age group. Children born to mothers with MG demonstrate transient weakness (‘neonatal MG’) in about 15% of cases.

The precise role of the thymus is uncertain, but ACh receptors (AChR) are present in the myoid cells of the normal thymus, and there is evidence that anti-AChR antibody production is mediated by both B and T lymphocytes of thymic origin.

Patients with MG have an increased incidence of other autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, Hashimoto thyroiditis, Graves' disease and pernicious anaemia; autoantibodies to other organs may be seen in MG patients without evidence of disease. [47] Other associations include myocarditis and lymphoma.

Several congenital myasthaenic syndromes exist, in which symptoms develop in infancy, childhood or rarely in adolescence. Congenital myasthenic syndromes comprise a group of early onset, genetic, antibody-negative neuromuscular transmission disorders due to mutations in proteins involved in the maintenance and function of the motor endplate (endplate myopathies). [48] Congenital myasthaenia syndromes are clinically characterised by abnormal fatigability, or transient or permanent weakness of extra-ocular, facial, bulbar, truncal, respiratory or limb muscles.

The stimulus to auto-antibody production in MG is not known. The antibodies interfere with neuromuscular transmission by competitively blocking receptor sites, initiating immune-mediated destruction of receptors, or binding to portions of the receptor molecule that are not part of the AChR site but nevertheless are important in allowing ACh to bind.

Clinical Presentation

Patients with MG typically present with fatigable muscle weakness. They commonly present initially with ocular manifestations such as asymmetrical fatigable ptosis with or without blurred or double vision due to ophthalmoplegia. The majority, however, evolve further into generalised muscle weakness involving the facial and bulbar muscles, the neck, axial muscles and the limbs. Upper limb weakness is commonly more severe than lower limb weakness. In severe cases (myasthenic crisis), there is neuromuscular dysphagia rapidly evolving into complete loss of swallow function, and often concurrent respiratory muscle weakness and type 2 respiratory failure. Bulbar muscle weakness is common and may result in nasal regurgitation, dysarthria and dysphagia. In 20% of cases, the disorder remains confined to the eye muscles (ocular MG). The phenotype of LRP4 antibody-associated MG remains uncertain.

Some patients complain of fatigue rather than weakness and may be misdiagnosed as having psychiatric problems. However, weakness can be elicited by a sustained effort of an involved muscle group (e.g. sustained upward gaze is often worse at the end of the day and improves with rest).

Investigations

Because most patients with generalised MG are treated with corticosteroids or other immunosuppressants or may need major surgery (thymectomy), the diagnosis of MG must be firmly established. Single-fibre electromyography and serologic tests for acetylcholine receptor antibodies (AChR-Ab) are the most reliable tests to confirm a diagnosis of MG.

AChR-Ab are present in 85% of generalised MG, and 40% to 55% of ocular MG. The presence of autoantibodies against nicotinic AChR is highly specific, but false positives may occur in patients with penicillamine-treated rheumatoid disease, other autoimmune diseases and in some first-degree relatives of patients with MG. Furthermore, assay methods influence test specificity, live cell-based assays have a higher specificity than radioimmunoprecipitation methods. [49] Other antibodies associated with MG include MuSK and LPR4 antibodies; the former is associated with a specific clinical phenotype and requires a unique treatment approach. A small proportion of patients remain seronegative using routinely available testing methods.

Electrophysiological test may demonstrate a compound muscle action potential amplitude/area reduction of more than 10% on low-rate repeated nerve stimulation, and increased jitter on single-fibre electromyography. Repeated nerve stimulation or single-fibre electromyography shows characteristic abnormalities in 90% of patients with generalised MG and in most patients with ptosis. In contrast, in patients with isolated diplopia, single-fibre electromyography does not exclude ocular MG. [50]

A syndrome of myasthaenic weakness occurs in association with malignancy and other autoimmune diseases (Eaton-Lambert or Lambert-Eaton syndrome). Although fatigability is present, the pelvic and thigh muscles are predominantly affected, whereas ocular and bulbar involvement is rare. Tendon reflexes are reduced or absent, and unique electrodiagnostic findings are seen along with autonomic neuropathy and the presence of antibodies to voltage-gated calcium channels. [51]

Management

Generalised MG

The traditional approach to the management of MG includes anticholinesterase therapy for symptomatic treatment (commonly pyridostigmine), along with immunosuppression (corticosteroids and either azathioprine or mycophenolate) to modify auto-antibody production; intravenous immunoglobulin and plasmapheresis are used for acute, severe presentations. Novel monoclonal antibodies that target B cells, complement, interleukin-6 and the Fc receptor either reduce auto-antibody production or degrade circulating antibodies.

The traditional approach to the management of MG is pharmacological and surgical and includes the following:

1. *Symptomatic treatment* is provided by anticholinesterase drugs, which potentiate the action of ACh at receptor sites. Pyridostigmine is the most used and is commenced at a dose of 60 mg orally three to four times daily. Considerable adjustment of dosage may be required based on symptom relief and side effects (diarrhoea, abdominal pain, cramps, urinary urgency and increased flatus, salivation and sweating).
2. Expert consensus and limited controlled trial data suggest that most patients require immunosuppression with a combination of *corticosteroids and/or azathioprine* . [52–54]
   Corticosteroids are the first-line immunosuppressive treatment for MG, independently of the immunological subtype. High doses of corticosteroids (e.g. prednisolone 50–100 mg/day or every second day) are used initially and may be introduced gradually, before being carefully reduced to the minimal dose required (10–40 mg/day) for symptom control. Transient exacerbation upon

commencement of steroids is very common, and severely affected patients are often hospitalised for the initiation of therapy with gradually increasing doses. Despite being considered the most effective oral immunosuppressant agent, corticosteroid side effects pose significant challenges in clinical use. Older patients are more likely to respond, but an average of 4 months' treatment is required to achieve clinical stability and the majority will require continuing treatment indefinitely. [55]

Azathioprine and mycophenolate are both effective adjuncts to corticosteroid therapy because a combination of corticosteroids with either agent allows a reduced dose of steroid, minimising the side effects of steroid therapy and achieving a better functional outcome overall. Azathioprine and mycophenolate are purine synthesis antagonists and have effects on T and B lymphocytes. Thiopurine methyltransferase activity should ideally be tested before treatment with azathioprine because low activity increases the risk of toxic side effects. [56], [57] Overall, 80% of patients are improved with a combination of steroids and either azathioprine or mycophenolate, but this may be seen only after some months. Furthermore, the clinical benefit of azathioprine as a steroid-sparing agent is not realised for approximately 18 months. [58] A few patients may eventually achieve complete remission.

Ciclosporin (cyclosporine), methotrexate and tacrolimus are all supported by limited evidence in MG and are occasionally used. [59–61]

3. *Thymectomy* offers the prospect of long-term, drug-free remission and has long been advocated as a mainstay of MG treatment. Thymectomy should be performed in patients with MG and a thymoma. Historical studies suggested that total thymectomy also benefited patients with MG without a thymoma. [62] This has been confirmed in a clinical trial supporting early total thymectomy for patients with generalised disease, duration of disease of less than 3–5 years and age of less than 65. [63] Thymectomy was associated with symptom reduction, less immunosuppressive drug treatment and fewer exacerbations during the 3-year follow-up.

Preoperative optimisation of neuromuscular function is essential, using anticholinesterase drugs and steroids, supplemented by plasma exchange or immunoglobulin if necessary. Though anticholinesterase requirements are usually reduced in the immediate postoperative period to about three-quarters of the preoperative dose, sustained improvement following thymectomy may not be seen for months or even years. A thoracoscopic approach may achieve equivalent results with less short-term morbidity, but the traditional sternotomy approach continues to be commonly used.

4. *Plasma exchange and intravenous immunoglobulin* are equally effective in producing short-term clinical improvement. [64–66] Either approach may be used in myasthaenic crisis or to improve severely affected patients before thymectomy. For *plasma exchange* , five exchanges of 3–4 L each are performed over a 2-week period and this results in improvement within days. However, the benefits are short-lived, lasting only weeks. *Intravenous immunoglobulin* can be used at a total dose of 1–2 g/kg given over 1–2 days, and occasional patients derive long-term benefits. Interestingly, immunoglobulin has no consistent effect on AChR antibody concentrations, and its mechanism of action is poorly understood.
5. Recent advances in the understanding of the pathophysiology of MG have led to novel approaches that are currently under evaluation. These include B cell depletion using monoclonal antibodies against CD19 or 20; complement inhibition; reduction of circulating IgG antibodies by binding and blocking Fc receptors; and Interleukin-6 receptor inhibition, reducing pro-inflammatory T and B cell differentiation. [67–69] Cost-effectiveness, side effect profiles related to extended use and combination with immunosuppressive therapy need further evaluation.

Muscle-specific tyrosine kinase antibody-mediated MG

Muscle-specific tyrosine kinase (MuSK) is a post-synaptic protein that is critical for the development and maintenance of the neuromuscular junction. Patients with MuSK auto-antibody-related MG (MuSK-MG) have important clinical differences when compared to AChR-Ab-MG. MuSK-MG also presents with fatiguable weakness, but compared to AChR-Ab-MG, patients have more bulbar, neck and respiratory muscle weakness, with less ocular and limb symptoms.[70] Symptom progression from onset can be rapid. Almost all patients have bulbar weakness which may not fatigue and can result in dysarthria, stridor, dysphagia and tongue weakness. Wasting and fasciculations of the tongue can be seen and must be distinguished from patients with bulbar motor neuron disease.[71] Some MuSK-MG patients present with symptoms indistinguishable from AChR-Ab-MG, and others present with head drop as their most prominent symptom. Females are more frequently affected than males.

Treatment of MuSK-MG differs from AChR-Ab-MG. MuSK-MG patients tend to respond less to pyridostigmine and other cholinesterase inhibitors and are more susceptible to nicotinic and muscarinic side effects. Clinical deterioration with pyridostigmine has been reported in MuSK-MG patients.

The initial immunotherapy approach is like that used for AChR-Ab-MG (corticosteroids, plasma exchange and IVIG), although IVIG appears to be less efficacious than plasma exchange. In MuSK-MG, unprovoked disease exacerbations and myasthenic crises frequently occur even despite high doses of immunosuppression. Traditional steroid-sparing agents such as azathioprine, mycophenolate mofetil, tacrolimus, methotrexate and cyclosporine appear to be less effective in MuSK-MG.

Rituximab should be considered as soon as possible to treat MuSK-MG patients who do not respond well to first immunosuppressive therapy, according to current consensus advice.[72,73] Most patients with MuSK-MG receiving rituximab show sustained clinical improvement. Rituximab has also led to a noticeable reduction in treatment-refractory cases.

Myasthaenic and Cholinergic Crisis

Patients with known MG may undergo life-threatening episodes of acute deterioration affecting bulbar and respiratory muscle function. These may occur spontaneously or may follow intercurrent infection, pregnancy, surgery, the administration of various drugs (Box 67.4) or attempts to reduce the level of immunosuppression. Such episodes, known as myasthaenic crises, usually resolve over several weeks, but occasionally last for months. The incidence of myasthaenic crisis increases markedly with age.

Rarely, a patient may deteriorate due to excessive dosage of anticholinesterase drugs (‘cholinergic crisis’). Abdominal cramps, diarrhoea, excessive pulmonary secretions, sweating, salivation and bradycardia may be present, but these can also occur in patients with myasthaenic crisis on high doses of pyridostigmine. Though the two situations may be difficult to distinguish, myasthaenic crisis is far more likely unless extremely large doses of pyridostigmine (at least 120 mg every 3 hours) have been administered.

The edrophonium (‘Tensilon’) test is now considered an unreliable method of distinguishing between these two possibilities and is not recommended.

Patients with myasthaenic crisis should be admitted directly to the ICU, as there is a significant risk of pulmonary aspiration due to bulbar involvement, bacterial pneumonia due to stasis, acute respiratory failure or cardiorespiratory arrest. After initial stabilisation and resuscitation, every effort should be made to identify and correct reversible causes, especially respiratory infections and electrolyte disturbances.

Frequent estimations of vital capacity and maximum inspiratory force should be made and recorded. Tracheal intubation and mechanical ventilation should be considered in patients with significant bulbar involvement or clinical evidence of worsening respiratory failure. As with other neuromuscular disorders, deterioration of blood gases may occur late and is an unreliable sign of progressive respiratory failure. [37] Aggressive chest physiotherapy, urinary drainage and nasogastric feeding may be required. Hypokalaemia, hypocalcaemia and hypermagnesaemia should be avoided, as all may exacerbate muscle weakness.

If the patient’s clinical status cannot be rapidly improved by the adjustment of anticholinesterase dosage, immunosuppressive therapy and aggressive treatment of intercurrent illness, high-dose corticosteroids and plasma exchange or immunoglobulin should be commenced simultaneously, and may produce some benefit within as little as 24 hours.

Perioperative Management

MG patients often require intensive care in relation to surgery for intercurrent illness or prior to thymectomy. Unstable patients should be admitted to hospital some days in advance for stabilisation. In severely affected patients, preoperative high-dose corticosteroids and/or plasma exchange may be used to improve the patient's fitness for surgery.

An anaesthetic technique that avoids the use of non-depolarising muscle relaxants and reversal agents has been historically advocated. However, the combination of incremental dosing of rocuronium, starting with 10% of the standard intubating dose, and guided by quantitative neuromuscular monitoring, followed by reversal with sugammadex, is now a common practice. [74]

Up to one-third of patients require continuing mechanical ventilation postoperatively following thymectomy. Predictive factors include a long preoperative duration of myasthaenia, coexistent chronic respiratory disease, high anticholinesterase requirements (e.g. pyridostigmine >750 mg/day) and a preoperative vital capacity of less than 2.9 L. [75] In those cases requiring mechanical ventilation, some authors advocate temporary cessation of anticholinesterase drugs to reduce respiratory secretions, but generally, they should be continued, though dosage requirements must be reassessed carefully and repeatedly.

Motor Neuron Disease (Amyotrophic Lateral Sclerosis, Lou Gehrig's Disease)

Motor neuron disease is a heterogeneous progressive, paralytic disorder characterised by gradual generalised degeneration of all types of motor neurons. [76], [77] This leads to physical disability associated with impaired cognition (frontotemporal dementia). Death usually occurs 3–5 years after diagnosis due to respiratory failure.

Pathogenesis

The key pathological finding is mixed upper and lower motor neurone death in the motor cortex and spinal cord, accompanied by inflammation and proliferation of astrocytes, microglia and oligodendrocytes.

Over 120 genetic variants of motor neurone disease have been identified and approximately 10% of cases are familial and 90% are sporadic.

Clinical Presentation

There are four main clinical phenotypes of motor neurone disease.

- Amyotrophic lateral sclerosis (ALS) is the dominant phenotype (70%) and presents with mixed upper and lower motor neurone signs affecting the limbs. This is the most malignant form of the disease and median life expectancy is about 3 years.
- Isolated bulbar palsy (4%–8%) presents initially with progressive speech and swallowing difficulty prior to the development of a more generalised disease.
- Progressive muscular atrophy (5%) presents with pure lower motor neurone signs affecting the limbs.
- Primary lateral sclerosis presents with pure upper motor neurone signs affecting the lower limbs mainly, with patients having a much slower disease progression and, in some cases, a normal life expectancy.

As motor neurone disease becomes more generalised, a mixed pattern of upper and lower motor neurone signs affecting limb skeletal muscle evolves (i.e. spasticity and hyperreflexia in addition to gross wasting) with bulbar and respiratory muscles also affected.

It is now recognised that up to half the patients have evidence of cognitive dysfunction, manifest as language difficulties and frontal symptoms.

Diagnosis

There are no specific investigations, and the diagnosis must be made on clinical grounds together with electromyogram evidence of generalised denervation. The most important differential diagnosis is multifocal motor neuropathy. The distinction is of clinical importance, as the latter is amenable to treatment. Poliomyelitis can also result in a syndrome of progressive weakness, wasting and fasciculation, beginning many years after the initial illness (the post-polio syndrome) and leading occasionally to respiratory failure and death. [78]

Management

Treatment is essentially symptomatic and supportive. Sleep-disordered breathing occurs early and may precede daytime respiratory symptoms and chronic respiratory failure; non-invasive ventilation improves both quality of life and survival in patients prior to the onset of bulbar dysfunction and has no role after the onset of bulbar pathology. [78-80] Riluzole, a centrally acting glutamate antagonist that also modifies sodium channel activity, has been shown to modestly slow slightly the progression of ALS by 3–6 months. [81–83]

Early multidisciplinary planning to establish advanced care directives is important.

Periodic Paralysis [84]

This term describes a group of rare primary disorders, mostly inherited as autosomal dominant traits, producing episodic weakness. They must be distinguished from other causes of intermittent weakness, including electrolyte abnormalities, MG and transient ischaemic attacks. The inherited types are now grouped together with the various forms of myotonia and susceptibility to malignant hyperthermia. All are classified as congenital defects of skeletal muscle ion channels and there is an association with long QT syndrome and other cardiac channelopathies. Symptoms begin early in life (before age 25), and follow rest or sleep rather than exertion. Alertness during attacks is completely preserved, and muscle strength between attacks is normal. Treatment is usually successful in preventing both the attacks and the chronic weakness, which can develop after many years in untreated patients.

The *hypokalaemic* form of periodic paralysis is a predominantly inherited condition in which genetic mutations affect the calcium or sodium channels in skeletal muscle. It can also present sporadically in association with thyrotoxicosis. Involvement of bulbar or respiratory muscles occurs rarely. The degree of hypokalaemia during attacks is mild, but patients rapidly respond to potassium administration. Effective prophylaxis is conferred by acetazolamide, with potassium replacement. Many patients eventually develop established myopathy. Depolarising muscle relaxants should be avoided in these patients.

The *hyperkalaemic* form is milder, almost always inherited (autosomal dominant with almost complete penetrance); it is associated with a genetic alteration in the gene that regulates the production of protein SCN4A in the sodium channel of skeletal muscle. The serum potassium is modestly elevated at the beginning of attacks but may be normal at other times. Creatine kinase levels may be elevated during attacks. Attacks respond to carbohydrate administration, sympathomimetics (which activate the sodium/potassium pump) and acetazolamide. Thiazide diuretics or acetazolamide provide effective prophylaxis. Relatively asymptomatic myotonia is not an uncommon clinical finding in between episodes of weakness. Non-depolarising muscle relaxants should be avoided in these patients.

A *normokalaemic* form and several eponymously named congenital syndromes are also included in this group of disorders.

Botulism[85]

Botulism is a very uncommon potentially lethal disease caused by exotoxins produced by *Clostridium botulinum* and, less commonly other species *Butyricum and Barati* . These are obligate anaerobic, spore-forming Gram-positive bacilli. The vast majority of botulism is *foodborne* and outbreaks are largely due to subtypes A, B, E, F, G and H. Signs and symptoms are caused by toxin produced in vitro and then ingested.

Wound botulism arises rarely when wounds (typically open fractures) are contaminated by soil containing type A or B organisms. Intravenous drug abusers are an increasing source of this condition through infected injection sites.

Infantile botulism arises in infants under 6 months of age and is due to the active production of toxin by organisms in the gut rather than the direct ingestion of toxin.

Hidden botulism describes the adult equivalent of infantile botulism, and is a rare complication of various gastrointestinal abnormalities.

Inadvertent botulism is the most recently described form and occurs as a complication of the medical or cosmetic use of botulinum toxin (BoNT).

Inhalational botulism is the form that would occur as a result of aerosolised toxin released in the context of bioterrorism. BoNT is the most potent known neurotoxin, and it has been estimated that as little as 1 g of aerosolised BoNT could lead to the death of over 1.5 million people.

In most cases, exogenously produced exotoxin is absorbed (primarily in the upper small intestine), and carried by the bloodstream to cholinergic nerves at the neuromuscular junction, postganglionic parasympathetic nerve endings and autonomic ganglia, to which it irreversibly binds. The toxin enters the nerve endings to interfere with ACh release.

Most patients become ill about 3 days after ingestion of the toxin, with gastrointestinal symptoms (nausea, vomiting, abdominal pain, diarrhoea or constipation), dryness of the eyes and mouth, dysphagia and generalised weakness, which progresses in a symmetrical, descending fashion, with ventilatory failure in severe cases. Cranial nerve dysfunction is a prominent early feature, manifested by ptosis and diplopia, facial weakness and impaired upper airway reflexes. The pupils may be fixed and dilated in severe cases. Patients are usually afebrile and have no sensory involvement.

The differential diagnosis includes food poisoning from other causes, MG and GBS. Botulism can be confirmed by the presence of toxin (either in the patient's serum or stool, or in contaminated food) in about two-thirds of cases. Contact tracing, in the case of foodborne botulism, is of great importance.

Treatment is mainly supportive, with airway protection and mechanical ventilation when required. Mean duration of mechanical ventilation, when required, is 7 weeks. Clearance of toxin from the bowel with enemas and cathartics has been advocated. Guanidine hydrochloride, which enhances the release of ACh from nerve terminals, has been reported to improve muscle strength, especially in ocular muscles, and may be useful in milder cases. Antibiotics have not been clearly shown to be useful. Botulinum antitoxins and immunoglobulins are now becoming available. Antitoxin must be given before the onset of paralysis to be effective. In *wound botulism* , antibiotics (penicillin or metronidazole) and aggressive debridement are recommended.

Most patients begin to improve after a week or so, but hospitalisation is usually required for 1–3 months. The mortality is low (5%–8%) with good supportive care, including mechanical ventilation. Mild weakness and constipation may persist for many months.

Diabetic emergencies and glucose control in the ICU

Mahesh Ramanan and Elif Ekinci

Introduction

Diabetes and its associated medical emergencies are increasing in prevalence globally, with 10.5% (536.6 million) of the adult global population living with diabetes in 2021. By 2030, this is expected to rise to 11.3% (642.7 million) with significant financial costs to the healthcare budget.[1,2] There were an estimated 1.2 million children and adolescents living with Type 1 diabetes in 2021, with a yearly incidence of 149,500 newly diagnosed cases.[3]

Diabetic emergencies can be classified as either hyperglycaemic or hypoglycaemic emergencies. Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycaemic state (HHS) are the two most common hyperglycaemic acute emergencies associated with diabetes. They are the result of absolute or relative insulin deficiency. The overtreatment of hyperglycaemia, with insulin typically, but also in combination with certain oral hypoglycaemic agents (OHA), can cause hypoglycaemia. Both hyperglycaemia or hypoglycaemia are associated with short- and long-term sequelae, mortality and place a substantial economic burden on healthcare systems worldwide.

The overall mortality rate associated with DKA is approximately 1% or less in high-income countries such as the United States, United Kingdom and Australia.[4–6] However, in limited-resource settings, mortality rates can be 10% or more.[7,8] HHS, on the other hand, though less frequent than

DKA, has a higher mortality rate of 10%–16%.[9,10] The all-cause 30-day mortality following a hyperglycaemic emergency was 2.8% in patients with type 2 diabetes, and 1.2% in those with type 1 diabetes in the United States.[11] The cost of managing DKA was estimated at GBP2064 (95% confidence interval GBP1800–2563) per DKA admission in the United Kingdom in 2014, 4400 AUD in Australia and 30,836 USD in the United States.[4,12–14] The mortality rate from DKA and HHS increased during the COVID-19 pandemic for patients who had concomitant COVID-19. The overall incidence of DKA also increased during the COVID-19 pandemic.[15,16]

Pathophysiology

Glucose metabolism is dependent upon the presence of insulin; both DKA and HHS result from an absolute or relative reduction in insulin activity. An accompanying elevation of counter-regulatory stress hormones, particularly glucagon, but also catecholamines, cortisol and growth hormone results in hyperglycaemia.

Hyperglycaemia occurs due to increased rates of gluconeogenesis and glycogenolysis, and reduction in tissue glucose utilisation. The increase in glucose production occurs in the liver and kidneys as there is a high availability of gluconeogenic precursors such as amino acids, lactate, and glycerol. Protein turnover shifts from balanced synthesis and degradation to reduced synthesis and increased degradation. Lactate and glycerol also become available for gluconeogenesis due to respective increases in skeletal muscle glycogenolysis and lipolysis in adipose tissue. Gluconeogenic enzyme activity, especially phosphoenol pyruvate carboxykinase (PEPCK) is also enhanced by stress hormones. The ensuing hyperglycaemia leads to glycosuria, osmotic diuresis, and dehydration once the renal glucose reabsorption threshold is breached. The resultant reduction in renal perfusion, due to dehydration and hypovolaemia, leads to a progressive decline in glomerular filtration rate and worsens hyperglycaemia in a positive feedback loop.[17]

Insulin deficiency and increased adrenaline levels activate hormone-sensitive lipase in adipose tissue, which leads to the breakdown of triglycerides into glycerol and free fatty acids (FFA).[18] Elevated glucagon:insulin ratios promote oxidation of FFAs to ketone bodies in the liver. Acetyl–Coenzyme A carboxylase is inhibited by glucagon with resultant reduction in synthesis of malonyl-Coenzyme A. Decreased malonyl-CoA concentration stimulates ketogenesis by stimulating carnitine O-palmitoyltransferase 1 (liver isoform) (CPT1-L), thereby promoting transesterification of fatty acylcarnitine and oxidation of FFA to ketone bodies.[19] Both cortisol and growth hormone are capable of increasing FFA and ketone levels and experiments conducted on pancreatectomised patients suggest that glucagon is not essential for the development of ketoacidosis but that it may accelerate the onset of ketonaemia and hyperglycaemia in insulin deficiency.[20] In DKA states, the metabolism and clearance of ketone bodies are decreased, leading to a further rise in ketone levels.[21] The main ketone bodies in DKA, aceto-acetic acid and its metabolites betahydroxybutyric acid and acetone are strong acids which dissociate freely at physiological pH with resultant acidaemia. Buffering the ensuing drop in pH depletes physiological alkali reserves. As ketone anions accumulate, the plasma anion gap expands. High concentrations of ketone bodies contribute further to osmotic diuresis. The resultant constellation of hyperglycaemia, glycosuria, osmotic dehydration and electrolyte depletion, ketonaemia and high anion gap metabolic acidosis is the typical phenotype observed in DKA.[22, 23]

DKA can also occur in patients receiving sodium glucose co-transporter-2 inhibitor (SGLT2i) medications used in diabetes management with broad metabolic, cardiovascular and renal benefits, and reduced longer-term mortality.[24–26] With the rapid uptake of SGLT2i medications, a special type of DKA, termed euglycaemic DKA (eDKA) because of the tendency for these patients to present with DKA with lower than expected blood glucose levels, is being increasingly recognised.[27, 28] Patients on SGLT2i medications are particularly prone to developing eDKA around times of fasting (e.g. in preparation for elective procedures or operations) and acute illnesses.[29–31] SGLT2i medications inhibit active reabsorption of filtered glucose from the proximal convoluted tubules of the kidneys, thereby inducing glycosuria and improving glycaemic control. They reduce the requirement for insulin, while concomitantly stimulating glucagon release from pancreatic alpha cells.[32] This elevates the glucagon:insulin ratio, while the glycosuria keeps the blood glucose level from being elevated. This combination leads to eDKA, which may be more difficult to diagnose given the absence of typical hyperglycaemia seen in conventional DKA.[33] It is therefore important to check ketones in any patients with diabetes if they are feeling unwell, especially if there is a history of use of SGLT2i. Of note, SGLT2i use is contraindicated in type 1 diabetes due to the increased risk of DKA.[34], [35]

In contrast to DKA, higher levels of basal and stimulated C-peptide in HHS suggest there is enough insulin present in HHS to prevent lipolysis but not enough to promote peripheral glucose utilisation, that is, a relative insulin deficiency.[36] In experimental animals, hyperosmolarity has been shown to directly inhibit lipolysis and FFA release from adipose tissue.[37] Ketogenesis, consequently, is usually absent in HHS. Moreover, patients with HHS have reduced levels of FFA, glucagon, cortisol and growth hormone as compared to patients with DKA.

HHS, as compared to DKA, has a slower onset with hyperosmolarity as a prominent feature. It is caused by prolonged osmotic diuresis with impaired ability to take adequate fluids, which accelerates once there is impairment of level of consciousness. Even with a normal conscious state, patients with HHS have impaired thirst reflexes. However, the hyperosmolarity seen in some patients with DKA results from a shorter duration of osmotic diuresis accompanied by reduced fluid intake and increased fluid loss due to nausea and vomiting, which is often ascribed to the brainstem effects of elevated ketones.

Hyperglycaemia results in a proinflammatory state, with a direct correlation between high blood glucose and increased mortality.[38] Both in DKA and non-ketotic hyperglycaemia, there is a significant rise of pro-inflammatory cytokines, including C-reactive protein, reactive oxygen species, cortisol, growth hormone and FFAs which often return to baseline within 24 hours of insulin therapy.[39] Insulin therapy is known to exert powerful anti-inflammatory effects.[40]

The inflammatory milieu in hyperglycaemic emergencies, along with dehydration, predisposes to a prothrombotic state. There is diffuse vascular injury and abnormalities of the coagulation cascade, platelet activation, blood flow and vascular reactivity. This may result in thrombotic events including deep vein thrombosis, ischaemic stroke and other thrombotic complications.[41,42]

Clinical Presentation and Diagnosis

DKA and HHS represent the two extreme metabolic complications of absolute and relative insulin deficiency. These should be suspected in every clinically unwell, hyperglycaemic patient presenting to the emergency department or in hospital under treatment. HHS develops insidiously over days to weeks, whereas the development of DKA is more acute with a prodrome lasting only hours to days (Table 68.1). DKA and HHS co-exist in up to 30% of cases.[36] In both DKA and HHS, polyuria, polydipsia, malaise and weight loss may be present. In DKA, nausea, vomiting and abdominal pain are key features observed in most patients. Abdominal pain, more common in children, could either be a symptom of, or precipitant of, DKA, and necessitates further investigations if it does not resolve with correction of dehydration and metabolic acidosis.[43,44] Dehydration results in loss of skin turgor, dry mucous membranes, thirst, tachycardia and hypotension. Mental obtundation occurs more frequently in HHS than DKA as more patients, by definition, are hyperosmolar and the presence of stupor or coma in patients who are not hyperosmolar requires consideration of other potential causes for the decrease in consciousness level.[21] Despite infection being a common precipitant in both DKA and HHS, most patients are either normothermic or hypothermic. Hypothermia could be a precipitant or due to vasodilatation and lack of substrate for cellular heat production,[45] and correlates with severity of DKA. Leukocytosis is a common feature in both DKA and HHS.

Table 68.1

Comparison of diabetic ketoacidosis and hyperosmolar hyperglycaemic state

PRESENTATION	DKA	HHS
Prodromal illness	Days	Weeks
Coma	+	+++
Blood glucose	++	+++
Ketones	+++	0 or +
Acidaemia	+++	0 or +
Anion gap	++	0 or +
Osmolality	++	+++

DKA , diabetic ketoacidosis; *HHS* , hyperosmolar hyperglycaemic state.

Diabetic Ketoacidosis

DKA is a potentially life-threatening metabolic complication of type 1 diabetes and ketosis-prone type 2 diabetes, especially in the context of SGLT2i use. Patients with DKA typically demonstrate hyperglycaemia, ketonaemia and metabolic acidosis; however, the absence of hyperglycaemia or ketonaemia does not always preclude the diagnosis of DKA. Kussmaul breathing, that is, compensatory hyperventilation for metabolic acidosis with deep, rapid, laboured breathing, is often present, and the breath may have the odour of acetone. The biochemical diagnostic criteria (American Diabetes Association) for DKA are [44] :

- Ketonaemia **or** ketonuria
  and

- Blood glucose >13.9 mmol/L **(>250 mg/dL)**

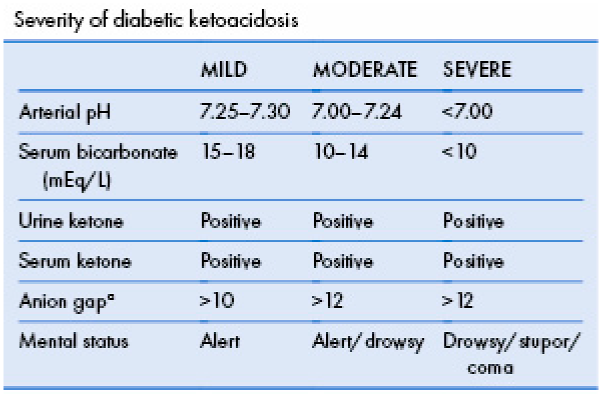
  and
- Serum bicarbonate (HCO_3^-) <18 mmol/L

  and
- Arterial pH < 7.3

  and
- Anion gap >10

For patients receiving SGLT2i therapy, hyperglycaemia is not required to make the diagnosis of DKA given the tendency for these patients to develop eDKA.[46] Severity of DKA is categorised by the American Diabetes Association into mild, moderate and severe as described in Table 68.2.[44]

Table 68.2



Severity of diabetic ketoacidosis

	MILD	MODERATE	SEVERE
Arterial pH	7.25–7.30	7.00–7.24	<7.00
Serum bicarbonate (mEq/L)	15–18	10–14	<10
Urine ketone	Positive	Positive	Positive
Serum ketone	Positive	Positive	Positive
Anion gap[a]	>10	>12	>12
Mental status	Alert	Alert/drowsy	Drowsy/stupor/coma

[a] Anion gap calculated as $[Na^+] - ([Cl^-] + [HCO_3^-])$

Adapted from American Diabetes Association Diabetic Ketoacidosis guidelines. See Reference.[41]

Non-adherence to insulin treatment, whether it be inability to access insulin injections due to misplaced prescriptions, or lack of access to insulin for other reasons, or insulin pump line failure or pump malfunction, concurrent use of sodium glucose co-transporter linked inhibitors (SGLT2i) infection, myocardial infarction or fasting in the context of perioperative period are the most common precipitants in developed nations, whereas infection and lack of access to healthcare are the leading precipitants in developing countries. [21] A UK survey identified the infection as the precipitant in 44.1% followed by non-adherence in 18.7% of patients, whereas as many as 7.8% of patients developed DKA during their hospital stay. [47] Patients developing DKA as inpatients, otherwise called ‘hospital-acquired DKA’, assume particular significance as this may reflect the quality of care, and is preventable. Underlying medical illness like myocardial infarction, pancreatitis and drugs affecting carbohydrate metabolism can also precipitate DKA. SGLT2i, in type 1 and type 2 diabetic patients, in the presence of risk factors like intercurrent illness, reduced oral intake and reduced insulin doses, have been linked with the development of serious, life-threatening DKA. [30, 48] Perioperative eDKA among patients receiving SGLT2i medications may be preventable with preoperative omission of these medications. A dose-response relationship between SGLT2i dose and risk of DKA has been demonstrated in analyses of clinical trials data from eight major randomised trials of SGLT2i use in patients with type 1 diabetes. [49]

In addition, numerous cases of fatal and near-fatal DKA have also been reported in patients on atypical antipsychotics. [50]

Hyperosmolar Hyperglycaemic Syndrome

HHS is commonly seen in elderly type 2 diabetes patients; however, younger presentations, often as an initial presentation of type 2 diabetes, may also occur. [51] Infections, in particular, pneumonia and urinary tract infections, are the most common precipitants. [52] Inadequate doses of insulin or oral anti-hyperglycaemic agents and certain drugs including diuretics, corticosteroids, β-blockers, phenytoin, antipsychotics and diazoxide are the other common triggers.

Characteristic features of patients with HHS are [53] :

- Hypovolaemia
- Marked hyperglycaemia (>30 mmol/L) without significant hyperketonaemia (<3.0 mmol/L) or acidosis (pH >7.3, bicarbonate >15 mmol/L)
- Serum osmolality >320 mOsmol/kg.

Neurological symptoms such as mental obtundation, confusion or seizures may correlate with the severity of hyperosmolality. The major differentiating biochemical features between DKA and HHS are the presence of severe hyperosmolality and severe hyperglycaemia without severe ketosis or acidosis in HHS.

Management

DKA and HHS are severe, life-threatening complications of diabetes and require prompt recognition and treatment (Table 68.3). The aims of treatment are fluid resuscitation to correct dehydration, termination of ketogenesis, restoration of biochemical milieu with insulin and electrolytes and prompt correction or treatment of underlying precipitant. Patients with HHS are at particular risk of thrombotic complications and require prompt thromboprophylaxis. Patients with a reduced level of consciousness may occasionally require airway protection with endotracheal intubation if consciousness level does not rapidly improve with resuscitation.

Table 68.3

Patients who may require high-dependency unit or intensive care unit admission

DKA	**HHS**
Blood ketones >6 mmol/L	Osmolality >350 mOsmol/kg
Bicarbonate <5 mmol/L	Sodium >160 mmol/L
K^+ <3.5 mmol/L	K^+ <3.5.0 mmol/L or >6.0 mmol/L
Venous/arterial pH <7.0	Venous/arterial pH <7.1
GCS <12 or abnormal AVPU	GCS <12 or abnormal AVPU
Oxygen saturation <92%, SBP <90 mm Hg, heart rate <60 or >100	Oxygen saturation <92%, SBP <90 mm Hg, heart rate <60 or >100
Anion gap >16	Urine output <0.5 mL/kg/h, Serum creatinine >200 µmol/L
	Hypothermia
	Macrovascular events such as myocardial infarction or stroke
	Other serious co-morbidities

AVPU , Alert, voice, pain, unresponsive; *DKA* , diabetic ketoacidosis; *GCS* , Glasgow Coma Scale; *HHS* , hyperosmolar hyperglycaemic state; *SBP* , systolic blood pressure.

Fluids

Fluid replacement and insulin administration are the mainstay of initial management, along with treatment of underlying cause (if not insulin non-adherence), of DKA and HHS. The objectives of fluid therapy are to restore circulatory volume, improve tissue perfusion and correct hyperosmolality. The total osmolar load on the kidney in DKA can be as much as 2000 mOsmol/day.[54] Fluid loss from osmotic diuresis is worsened by reduced reabsorption of salt, water and phosphate in the kidney, a direct effect attributable to lack of insulin.

Fluid alone will reduce levels of glucose and counter-regulatory hormones and reduce insulin peripheral resistance. Insulin therapy drives extracellular water into the intracellular space and can exacerbate hypovolaemia and hypernatraemia. It can also cause hypokalaemia. Insulin also results in a rapid fall in blood glucose concentration, thereby reducing serum osmolality. Rapid fluctuations in sodium concentration and osmolality can result in pontine or extrapontine myelinolysis. Hence, it is critically important to initiate fluid therapy early. However, aggressive fluid replacement, especially with hypotonic solutions, and especially in children and in those with cardiac and renal dysfunction, could lead to cerebral oedema, thus worsening the outcome.[55–57] Hyperosmolality should be corrected cautiously at a rate no faster than 3 mOsmol/kg H_2O/h.

Isotonic crystalloids are generally the fluids of choice for rehydration of patients with DKA and HHS. In the absence of strong, high-quality evidence to support the use of a particular type of crystalloid,[58] 0.9% sodium chloride ('saline') is the most widely recommended and used fluid owing to its ready availability, low cost and clinician familiarity.[44, 59, 60] However, buffered multielectrolyte crystalloid solutions (BMES), such as compound sodium lactate (also known as Hartmann's solution) and Plasmalyte-148, are being increasingly used due to their biochemical advantages.[61] BMES have chloride concentrations and osmolality (in the case of Plasmalyte-148) closer to normal human plasma, have an alkalinising effect on plasma arising from their buffer (lactate, acetate, gluconate), and result in a lesser degree of hyperchloraemic metabolic acidosis during the resolution phase of DKA.[62] Some evidence supports improved biochemical outcomes (faster resolution of DKA, lower post-resuscitation chloride concentrations) and clinical outcomes such as shorter

ICU and hospital length of stay with the use of BMES compared to saline.[63, 64] However, definitive data to guide choice of fluids is currently lacking.[65]

Infusion of 15–20 mL/kg of crystalloids in the first hour and subsequent fluid guided by vital signs such as heart rate, blood pressure, laboratory values and clinical examination should correct the fluid deficits in the first 24 hours.[3] Typically, patients with DKA have a fluid deficit of 60–100 mL/kg, which will require replacing in the first 24 hours of therapy along with additional fluid for maintenance and offsetting ongoing losses. Ten percent dextrose is added to the replacement fluid once blood sugar falls below 14 mmol/L to avoid hypoglycaemia and also importantly to allow the continuation of insulin infusion to suppress ketogenesis.[44, 60]

Insulin Therapy

Low-dose, physiological insulin replacement resolves the biochemical abnormalities as quickly as higher doses without running the risk of hypoglycaemia and hypokalaemia, which can be detrimental; gradual correction of hyperglycaemia is associated with lower mortality.[66, 67] In addition to correction of hyperglycaemia, insulin suppresses ketogenesis and lipolysis. In DKA, a bolus dose of insulin (0.1 Unit/kg) at the initiation of therapy could risk hypoglycaemia and is not routinely recommended unless there is a delay in commencing the weight-based fixed rate intravenous insulin infusion (FRIII) at 0.05–0.1 Unit/kg per hour. In HHS, FRIII at 0.05 Unit/kg per hour is recommended once the initial fluid resuscitation has taken place. Glucose decrement is the same irrespective of the route chosen; however, for critically ill patients, intravenous infusion of regular human insulin should be used. Metabolic targets like increasing bicarbonate concentration by 3 mmol/L per hour, reducing the blood glucose concentration by 3 mmol/L per hour and reducing the blood ketone concentration by 0.5 mmol/L per hour whilst maintaining normal potassium levels are typically used to guide insulin therapy. If the glucose levels fail to reduce appropriately, it may indicate insufficient fluid resuscitation. Severe insulin resistance can occasionally occur and will necessitate the use of higher doses. Along with insulin infusion, subcutaneous long-acting insulin analogues should be continued. This is to avoid hyperglycaemia and facilitate transition to usual subcutaneous insulin regime at the cessation of insulin infusion.[68] In DKA, FRIII should be continued until the resolution of ketoacidosis as evidenced by blood ketone levels of less than 0.6 mmol/L, venous pH over 7.3 and/or venous bicarbonate over 18 mmol/L.[44], [59] In HHS, however, insulin infusion should only cease with the correction of mental obtundation and normalisation of serum osmolality.[21]

Electrolyte Therapy

Potassium

Initially in DKA, hyperosmolality and acidosis cause a shift of potassium from intracellular to extracellular compartment. This potassium is lost because of osmotic diuresis. Renal losses are augmented by secondary hyperaldosteronism and keto-anion excretion as potassium salts. Despite total body deficits (Table 68.4), the measured potassium at presentation is usually normal or high but replacement should commence once potassium is less than 5.5 mmol/L. DKA patients may rarely present with very low potassium (less than 3.3 mmol/L). This represents profound potassium depletion (600–800 mmol) and could be life-threatening and replacement at 20 mmol/h should commence immediately with fluid therapy. Insulin therapy should only be initiated only when potassium level is more than 3.5 mmol/L. The combination of need for insulin therapy and potassium depletion at presentation can result in persistent and profound hypokalaemia during the treatment of DKA. This could predispose the patient to fatal arrhythmias and death. Pre-emptive treatment with supplemental potassium, intravenous initially, followed by combined intravenous and enteral potassium once nausea and vomiting have resolved, is an essential component of management.

Table 68.4

Typical deficits in diabetic ketoacidosis and hyperosmolar hyperglycaemic state

	DKA	HHS
Water	100 mL/kg	100–220 mL/kg
Sodium	7–10 mmol/kg	5–13 mmol/kg
Potassium	3–5 mmol/kg	4–6 mmol/kg
Chloride	3–5 mmol/kg	5–15 mmol/kg

DKA , diabetic ketoacidosis; *HHS* , hyperosmolar hyperglycaemic state.

Phosphate

In DKA, the typical total body phosphate deficit is about 1 mmol/kg, but serum phosphate is usually normal at presentation. Routine phosphate replacement has not been shown to be beneficial in DKA, [69] but correction of severely low levels (<0.4 mmol/L) may be necessary as this may lead to muscle weakness, impaired cardiac function and haemolytic anaemia. Excessive phosphate replacement may cause hypocalcaemia and calcium should be monitored. Insulin therapy also results in intracellular shift of phosphate and necessitates ongoing phosphate replacement. Oral replacement of phosphate in patients with critical illness has been shown to be as effective as intravenous replacement. [70]

Magnesium

A chronic magnesium deficiency may be present in type 1 or 2 diabetes and may be exacerbated by renal impairment. The benefits of magnesium replacement have not been demonstrated in diabetic emergencies, but the principles of magnesium supplementation are like in other critical care situations.

Bicarbonate

Use of bicarbonate for correction of acidosis in DKA is controversial and is not routinely recommended. Side effects like paradoxical intracellular acidosis, hypokalaemia, and altered tissue oxygenation may overshadow any potential benefits. In the context of DKA, sodium bicarbonate also delays the clearance of ketones and may enhance further hepatic production even when insulin and glucose are being delivered. [71] Except for life-threatening hyperkalaemia, bicarbonate administration is generally not recommended in DKA or HHS.

Monitoring

The recognition that blood glucose is only a surrogate of the metabolic derangement in DKA has shifted the focus of management to ketonaemia. Ketonuria may persist up to 2 days after the correction of acidosis due to the presence of aceto-acetate and acetone. Moreover, urine ketone strips, which detect aceto-acetate and are semiquantitative, may not truly be reflective of serum conditions, and their use has declined in most well-resourced settings. During the resolution of DKA, beta-hydroxybutyrate (β-OHB) is converted to aceto-acetate to be excreted in the urine. Thus the use of urine strips for monitoring may actually show a paradoxical increase in ketones while despite resolution of DKA.

There is a significant correlation between serum and capillary β-OHB and glucose. [72] This makes point-of-care (POC) blood tests for ketones, which measure beta-hydroxybutyrate, [73] glucose, electrolytes, bicarbonate and pH measurement are the cornerstone of the management of DKA. POC meters allow for not only rapid and accurate diagnosis but monitoring as well. Accurate measurement of β-OHB, the main ketoacid in DKA, with blood ketone meters has been one of the biggest advancements in the management of DKA. [74]

It is important to note that ketonaemia interferes with the Jaffe's picric acid method of measuring serum creatinine. Enzymatic methods of measuring creatinine can be used to avoid this interference. [75]

In HHS, serum osmolality can be measured with an osmometer or estimated osmolarity. Regular monitoring of neurological status includes the Glasgow Coma Scale and computed tomography (CT) scans as indicated for persistent coma or worsening neurological status.

DKA is considered to be resolved when blood glucose concentration <11.1 mmol/L and any two out of pH >7.3, bicarbonate >15 mmol/L or anion gap <12. [44]

The resolution of HHS is indicated by return to normal plasma osmolality and recovery from mental obtundation.

Complications of Diabetic Ketoacidosis and Hyperosmolar Hyperglycaemic State

Hypoglycaemia and Hypokalaemia

Hypoglycaemia and hypokalaemia are the most frequently occurring serious complications during the management of DKA, usually due to overtreatment with insulin or inadequate provision of glucose, and inadequate replacement of potassium, respectively. UK data suggested that over a quarter of these patients can develop hypoglycaemia, whereas the incidence of hypokalaemia was 55%. [47] Both hypoglycaemia and hypokalaemia can be fatal without prompt treatment, but can also be easily prevented and treated with proactive management. Thus strict attention is required to ensure adequate provision of glucose and potassium.

Cerebral Oedema

Clinically apparent cerebral oedema is rare (0.5%–1%) but an extremely serious complication of DKA occurring predominantly in children; the mortality is high (25%), with a quarter of survivors being left with some permanent neurological sequelae. Studies have suggested a subclinical incidence approaching 50%. [76] Risk factors for developing cerebral oedema include degree of hypocapnia and dehydration, the failure of serum sodium to rise with treatment and the use of sodium bicarbonate. [77] It can also occur in adults and may be associated with rapid deterioration in consciousness level with or without seizures. If progressive signs of brainstem herniation are present, the mortality is high, with only 7–14% likely to make a complete recovery. The risks of brain herniation are related to the degree of acidosis and the volume of initial fluid resuscitation. Oedema formation most likely occurs due to a vasogenic mechanism [78] and cerebral hyperaemia with loss of autoregulation evident; this can take up to 36 hours to resolve. [79]

Hyperchloraemic metabolic acidosis

The renal elimination of large amounts of keto-anions produced during DKA requires co-elimination of cations (principally sodium) to maintain electroneutrality. The chloride anions that are normally excreted along with sodium are hence retained and this leads to hyperchloraemia and hyperchloraemic metabolic acidosis. [80] The chloride load from resuscitation fluids also contributes to hyperchloraemia. Hyperchloraemic metabolic acidosis has been associated with worse outcomes for critically ill patients, and in patients with DKA leads to prolonged ICU and hospital admissions. Some degree of hyperchloraemia is unavoidable in DKA, but this may be limited by the use of BMES. [62, 81]

Other Complications

Pulmonary oedema is usually iatrogenic, and myocardial infarction can occur, particularly in the elderly. In HHS various neurological complications, including reversible tetraplegia, amnesia and optic atrophy have been described. HHS is also associated with increased in venous thrombo-embolic disease. Thromboprophylactic measures, both mechanical and chemical, should be rapidly instituted for prevention. [42, 53]

The metabolic acidosis of DKA generates a compensatory tachypnoea. The ensuing respiratory alkalosis partially compensates for acidaemia. Any event which blunts this tachypnoea, such as fatigue or induction of anaesthesia for endotracheal intubation, may lead to acute worsening of acidaemia and resultant decompensation. Thus the need for endotracheal intubation of patients with DKA, particularly severe DKA, must be balanced against this risk. Particular care must be taken in ensuring that a higher-than-usual minute ventilation is maintained during induction of anaesthesia and appropriate ventilator settings are prescribed afterwards. [82, 83]

Key practice points for clinicians to keep in mind when managing patients with DKA or HHS as listed in Box 68.1 .

Box 68.1

Key practice points for management of DKA and HHS

Prevention of Hyperglycaemic Emergencies

Patient information and education programs on home monitoring of glucose and ketones and recognition of early signs of hyperglycaemic emergencies could prevent emergency department and hospital admissions.

Hypoglycaemia

Hypoglycaemia (blood glucose concentration <3.9 mmol/L) is the most common and frequently underreported sequel to insulin and OHAs. The self-treated form is classified as ‘mild’ whereas it is ‘severe’ if external help is required for recovery. Hypoglycaemia can also be classified into three levels based on the depth of hypoglycaemia and requirement for external help (Table 68.5). [84] Any blood glucose of less than 4 mmol/L should be treated. Hypoglycaemia may lead to an impaired counter-regulatory system and, hence, nonspecific and relatively insensitive neuroglycopaenic symptoms and hypoglycaemia unawareness. [85] The incidence therefore is difficult to quantify. Data from a 2009 study conducted in the UK showed that patients with type 1 diabetes experience about two episodes of symptomatic hypoglycaemia per week and 1.0–1.7 episodes per patient-year of severe hypoglycaemia. [86] The UK hypoglycaemia study showed that the incidence of hypoglycaemia in type 2 diabetes can be as high as 25% as the disease approaches the insulin-deficient end of the spectrum. [87] More recent data from 2023 showed much lower rates of hypoglycaemia, 29.5 episodes per 100 patient-years for adult patients with type 1 diabetes, with even lower rates (9.8 episodes per 100 patient-years) when these patients were transitioned onto closed-loop insulin therapy.[88]

Table 68.5

Levels of hypoglycaemia

Level	Glycaemic description
Level 1	Glucose <70 mg/dL (3.9 mmol/L) and ≥54 mg/dL (3.0 mmol/L)
Level 2	Glucose <54 mg/dL (3.0 mmol/L)
Level 3	A severe event characterised by altered mental and/or physical status requiring assistance for treatment of hypoglycemia

Adapted from the Endocrine Society's Severe Hypoglycaemia guidelines (see reference 73)

Risk factors for developing hypoglycaemia include elderly patients, alcohol, early pregnancy, renal and hepatic impairment, strict glycaemic control, previous history of severe hypoglycaemia, sulfonylureas, administration of wrong insulin product and abrupt reduction in food intake.[59], [89]

The adverse effects of hypoglycaemia range from autonomic symptoms (sweating, palpitations, shaking) to transient impairment in the level of consciousness to permanent neurological damage and increased risk of death even at 1 year after discharge.[90], [91] It can cause seizures, hemiparesis, coma, arrhythmias, prolonged QT interval[92] and contributes to increased cardiovascular morbidity and mortality. Much of these effects result from brain neuronal glucose deprivation and hypoglycaemia-induced sympathoadrenal activation.

In-Patient Hypoglycaemia

Hypoglycaemia in hospitalised patients is seen both in patients with and without diabetes. Hypoglycaemia not triggered by glycaemic lowering agents (spontaneous hypoglycaemia) may be a manifestation of severe illness, for example severe sepsis, acute renal failure or acute liver failure. Attempts should be made to diagnose the underlying disease, as hypoglycaemia is an independent risk factor in increased length of hospital stay and mortality. One study quoted a 66% increased risk of death within 1 year and about 3 days longer stay in patients who experienced hypoglycaemia compared to those who did not. [90] Over 29% of DKA patients treated with FRIII suffered from hypoglycaemic episodes. [47] Episodes of severe hypoglycaemia are more prevalent in patients with type 1 diabetes and nocturnal episodes are particularly so.

Potential causes of in-patient hypoglycaemia are summarised in Box 68.2 . Insulin prescription errors, need for fasting, change in TPN or nasogastric feeding and changes in corticosteroid therapy doses are all potential causes of in-patient hypoglycaemia.

Box 68.2

Potential causes of in-patient hypoglycaemia

- Errors in insulin and OHA administration – inappropriate use of ‘stat’ or ‘PRN’ rapid/short-acting insulin, incorrect type or inappropriately timed insulin or OHA administration, IV insulin infusion without glucose infusion, inadequate mixing of mixed insulin
- Missed meals or inadequate carbohydrate intake. Typical examples in the hospital setting include changes to TPN or nasogastric feed regimens, fasting for procedures
- Acute discontinuation of long-term corticosteroid therapy or reduction in corticosteroid doses
- Severe illness
- Prolonged starvation times (i.e. ‘nil by mouth’)

- Drug interactions – concomitant administration of hypoglycaemic agents with warfarin, quinine, salicylates, MAO inhibitors, NSAIDs
- Endocrinal disorders (hypothyroidism, hypopituitarism, Addison’s disease) leading to loss of counter-regulatory hormone production

IV , Intravenous; *MAO* , monoamine oxidase; *NSAIDs* , non-steroidal anti-inflammatory drugs; *OHA* , oral hypoglycaemic agents.

Adapted from Joint British Diabetes Societies Inpatient Group (see reference [52])

Management of Hypoglycaemia

The majority of hypoglycaemic episodes are preventable. Meticulous attention to factors mentioned in Box 68.2 will help to mitigate the incidence of hypoglycaemia. Patients who have hypoglycaemia caused by OHAs will require prolonged monitoring due to the long duration effect of these medications. Down-titration of corticosteroids can also precipitate hypoglycaemia.

Initial treatment of hypoglycaemia depends on the patient’s conscious level. For patients who are alert and able to swallow, oral carbohydrates (equivalent to 15–20 grams of glucose) in the form of glucose tablets, sugar dissolved in water or fruit juice may be administered. If the patient cannot swallow and requires parenteral treatment, 200 mL of 10% dextrose solution (or equivalent volume of 20%, 25% or 50% dextrose solution depending on availability) should be administered. [93] Standard resuscitative measures including attention to airway, breathing and circulation should be initiated simultaneously.

The key steps following initial treatment are-

1. Repeat blood glucose in 10–15 minutes
2. Repeat initial steps if blood sugar remains less than 4 mmol/L.
3. Glucagon (1 mg intramuscular) may be used in insulin-induced hypoglycaemia, should only be administered once and non-

responders should receive intravenous dextrose.

4. Administer long-acting carbohydrate, such as biscuits, bread or a normal carbohydrate-containing meal, once blood sugar is more than 4 mmol/L. For critically ill patients, enteral (or parenteral, as appropriate) nutrition should be initiated, recommenced or uptitrated. 10% or 5% dextrose infusion may be required to maintain normoglycaemia if enteral/parenteral nutrition is contraindicated.
5. Insulin should not routinely be omitted. Dose adjustment may be required.

In patients experiencing hypoglycaemia, Diabetes UK's policy to 'make four the floor' recommends 4 mmol/L as the threshold of treatment in patients with diabetes. Nevertheless, adults experiencing hypoglycaemic symptoms with blood glucose levels of more than 4 mmol/L should receive prompt treatment as well. [93]

Glycaemic Management in Critical Illness

In health, serum glucose concentrations are tightly regulated between 4.0 and 7.8 mmol/L. However, during an episode of critical illness, both patients with and without diabetes can experience stress-induced hyperglycaemia due to a range of hormonal, inflammatory and metabolic changes. [94–101] Activation of the sympathetic nervous system leads to increased circulating levels of catecholamines (noradrenaline and adrenaline), cortisol and glucagon which increase glycogenolysis and gluconeogenesis and reduce glucose uptake in peripheral tissues. The systemic inflammatory response and its cytokine mediators increase insulin resistance in the peripheral tissues. Treatment factors such as the use of catecholamine vasoactive agents, corticosteroids, enteral and parenteral nutrition can also contribute to hyperglycaemia.

Stress-induced hyperglycaemia has been linked with a variety of adverse effects, and potentially contributes to morbidity and mortality in critical illness. [102–105] It can compromise immune function by impairing neutrophil activity, reduced phagocytosis and altered cytokine production.

Hyperglycaemia is thought to contribute to endothelial dysfunction and a prothrombotic state with resultant increase in risk of thrombosis and microcirculatory dysfunction. Hyperglycaemia exacerbates oxidative stress, with increased production of reactive oxygen species which cause cellular injury. Wound healing is impaired by hyperglycaemia. Osmotic diuresis from hyperglycaemia can lead to dehydration and electrolyte disturbances.

Based on these findings, it was hypothesised that normalisation of blood glucose concentrations using intravenous insulin infusion could mitigate the harms of stress-induced hyperglycaemia during critical illness. A pivotal randomised trial provided evidence that supported this hypothesis (by demonstrating a highly significant reduction in mortality with strict glycaemic control) and subsequently, strict glycaemic control was widely adopted in ICUs.[106] This was soon followed by another trial conducted by the same group in medical ICU patients demonstrated significant mortality reduction in the subgroup of patients who required ICU admission longer than 3 days.[107] However, despite these findings, some doubts persisted and several trials failed to replicate the previous findings of mortality benefit, instead demonstrating more episodes of hypoglycaemia with strict glycaemic control.[108–111] A large, multicentre, multinational, trial published in 2009 demonstrated significantly increased incidence of hypoglycaemia and higher mortality with strict glycaemic control.[112] This led to a re-evaluation of glycaemic targets in critical illness, with less emphasis on strict glucose control, and more emphasis on hypoglycaemia avoidance.[113] More recent evidence from a large contemporary trial which used a computer-algorithm-guided glycaemic control strategy has confirmed that there is no role for the widespread adoption of strict glycaemic control.[114] Research focus has shifted to personalised glucose targets, protocolised insulin infusion algorithms, continuous glucose monitoring and feedback-loop controlled delivery of insulin.[115, 116]

Polyuria in the ICU – diabetes insipidus and other causes

Alastair Craig Carr

Critically unwell patients seldom determine their own fluid and solute intakes; these are determined by clinicians. Prescriptions present fluid and solute loads, and critical illness may alter renal, gut and endothelial function, influencing fluid shifts between body compartments. Fluids and solutes may accumulate or be excreted depending upon the nature, stage and management of the illness. Dynamic changes in urine output are common.

Polyuria describes urine production >3 L/day or >30 mL/kg/day in an adult and >2 L/m ^{2} in children. When assessing polyuria, the intensivist must consider whether this is appropriate or inappropriate and physiological or pathological. A systematic, reiterative approach to assessment, investigation and diagnosis is necessary given the many causes of polyuria in critical illness (Box 69.1).

Box 69.1

Causes of polyuria

1. Water diuresis:
    a. Pathological
        Diabetes insipidus: cranial, nephrogenic, gestational
    b. Physiological

        - Psychogenic polydipsia (excess drinking is pathological but the diuresis is not)
        - Iatrogenic – excessive administration of hypotonic solutions, for example
            - 5% dextrose solution,
            - 0.45% saline,
            - 0.18% saline 4% dextrose solutions

2. Solute diuresis:
    a. Pathological
        - Hyperglycaemia
        - Azotaemia (uraemia [1])
        - Cerebral salt wasting
        - Fanconi's syndrome
        - Renal tubular acidosis
        - Glomerulonephritis
        - Hyperaldosteronism
        - Addison's disease
        - Anorexia nervosa
        - Migraines
        - Paroxysmal tachycardia (via increased atrial natriuretic peptide release)
        - Poisons/drugs:
            - Ethanol
            - Methanol
            - Ethylene glycol
            - Mannitol
            - Loop diuretics
            - Thiazide diuretics

    b. Physiological
        - Resolving sepsis (redistribution of fluid into the vascular compartment from the third space)
        - Post-obstructive diuresis (clearance of excess sodium, urea and other solutes)
        - High protein feeds (increased urea and amino acid clearance)

Iatrogenic – excessive administration of isotonic or hypertonic solutions, for example
- 0.9% saline
- hypertonic saline
- Hartmann’s solution

Background Physiology and Anatomy

Understanding normal regulation of fluid balance, urine production and osmolality, as well as standard investigations, aids clinical assessment and management planning.

Osmolality, Osmolarity and the Osmolal Gap

- An **osmole** is the amount of solute that dissociates in solution to form one mole (6.02×10^{23}) of osmotically active particles.
- **Osmolarity** measures osmoles of solute **per litre** of solvent; it is temperature dependent. **Osmolality** measures osmoles of solute **per kilogram** of solvent; it is temperature independent. Both include permeant (e.g. urea) and impermeant (e.g. sodium) solutes and change with water or permeant solute movement.
- **Osmolal gap** is the difference between calculated and measured osmolality (<10 mOsmol/kg in health). Values >10 mOsmol/kg indicate the presence of unmeasured osmotically active solute(s).

Normal plasma osmolality lies in a population range of 275–295 mOsmol/kg (265–285 in pregnancy) and individuals usually vary less than ±1% around their set value. Several equations provide estimates. [2] Worthley’s [3] correlates well with measured values. [4] In chronic renal disease, estimated osmolality may under-estimate measured osmolality progressively with worsening severity of disease. [5]

$$\text{Plasma osmolality}\left(\text{mOsmol/kg}\right) = 2\left[\text{Na}^{+}\right] + \left[\text{Urea}\right] + \left[\text{Glucose}\right]$$

All units of solute are mmol/L.

Actual and estimated osmolality differ in the presence of unmeasured, osmotically active solutes such as alcohols or mannitol. When considering hyper- or hypo-osmolality, measurement of freezing point depression of the plasma and/or urine is recommended. Increasing osmolality results in freezing point depression, both being colligative properties.

Tonicity

Tonicity describes the ability of a solution of impermeant solute to cause the movement of water between itself and another fluid compartment. Plasma tonicity is largely determined by sodium which cannot cross freely into intracellular from extracellular compartments. This facilitates the control of extracellular fluid volume through the regulation of sodium balance.

Tonicity and Osmolality of Commonly Prescribed Fluids

Compared to the intercellular milieu the following approximations are often used:

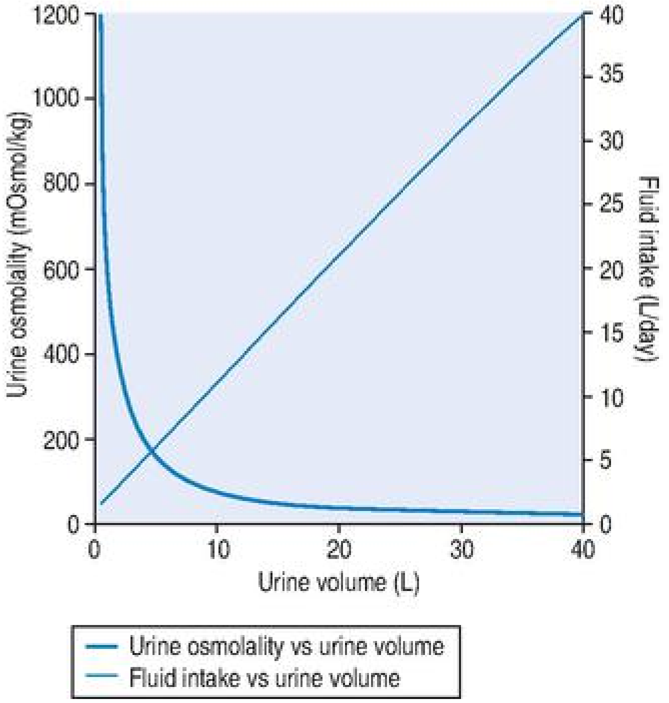
- 5% dextrose solution is hypotonic and iso-osmolar containing no impermeant solute (assuming no absence of insulin, glucose freely enters the cell).
- 0.9% NaCl and Hartmann's solution are considered isotonic and iso-osmolar.
- 3% NaCl solution is hypertonic and hyperosmolar.

Solute and Water Intake and Losses

Assuming a normal diet, a 75 kg human has obligatory solute losses of around 800 mmol/day (approximately 300 mmol urea and 500 mmol cations/anions). Maximum concentrating ability of healthy kidneys approximates 1200 mOsmol/kg. Consequently, 666 mL/day is the minimum urine output required to excrete osmotically active solutes. Insensible water losses approximate 10 mL/kg/day and rise with fever and hot, dry climates. Minimum obligatory water losses therefore total around 1.5 L/day.

Urinary Osmolality and Sodium

Urinary osmolality is normally between 500 and 700 mOsmol/kg with maxima of 1200 and minima of 25 mOsmol/kg. Obligatory solute excretion is relatively constant in health, so urine osmolality falls in response to increased free water intake and rises in response to dehydration (Fig. 69.1).



The graph depicts urine output and urine osmolality relative to increasing water intake in healthy individuals. The horizontal axis shows urine volume in litres, ranging from 0 to 40. The vertical axis on the left shows urine osmolality in milliosmoles per kilogram, ranging from 0 to 1200, and fluid intake litres per day, ranging 0 to 40. Urine osmolality vs urine volume curve shows a downward trend from 1200 milliosmoles per kilogram to 0 milliosmoles per kilogram, 40 litres urine volume. Fluid intake vs urine volume a downward trend from 40 litres per day to 0 litres per day.

FIG. 69.1 Urine output rises and urine osmolality falls in health as a function of increasing water intake. Assuming normal solute ingestion, normal solute excretion (around 800 mmol/day) is preserved between water intakes of 1.5 and 32 L/day.

Normal urinary sodium excretion sits between 40 and 220 mmol/day; this may be altered by disease, salt intake and medications. Urinary sodium concentrations are problematic to interpret without prior clinical assessment of fluid status, disease and medications. In health, <20 mmol/L implies salt conservation, whereas concentrations >40 mmol/L imply salt excretion.

Water and Solute Diuresis

Diuresis refers to urine output >1.5 mL/kg/h.

Water diuresis occurs when total daily solute excretion is normal, but urine osmolality is low.

Osmotic (solute) diuresis occurs when total daily solute excretion is elevated; the urine passed may be:

- iso-osmolar to plasma if the extracellular fluid volume is expanded or hyper-osmolar to plasma if the patient is hypo- or euvolaemic.

Plasma Osmolality and Plasma Volume Regulation

Plasma osmolality and volume are regulated by separate mechanisms. Changes can occur in tandem or independently. Maintenance of volume takes precedence over maintenance of osmolality.

Plasma volume is regulated via both volume and sodium receptors. These

- modulate sympathetic nervous (SNS) and renin-angiotensin-aldosterone (RAAS) systems
- alter hypothalamic-mediated 8-arginine-vasopressin (AVP) release (also known as antidiuretic hormone)
- modulate release of atrial natriuretic peptide (ANP) from atrial myocytes and B-type natriuretic peptide (BNP) from ventricular myocytes. These inhibit the release of renin, aldosterone, AVP and endothelin, leading to both natriuresis and diuresis. [6]

Water balance and osmolality are regulated via:

- thirst and subsequent fluid ingestion. Stimulants of thirst include:
  - plasma osmolality >290 mOsmol/kg
  - elevated angiotensin-II (A-II) concentrations
  - SNS activation
  - circulating volume depletion of 5%–10%
- AVP production/release
- renal fluid and solute elimination via the kidney
- metabolic solute clearance, for example glucose and ethanol.

Supraoptic (SON) and Paraventricular (PVN) Nuclei and AVP Production

AVP is a nonapeptide synthesised in hypothalamic paraventricular (PVN) and supraoptic (SON) nuclei, with configurational similarities to oxytocin, conferring some functional and receptor cross-reactivity.[7] It is transferred bound to neurophysin and copeptin, via axons:

- in the pituitary stalk, for storage in the posterior pituitary.
- terminating in the median eminence releasing AVP and oxytocin for transport to the anterior pituitary wherein they stimulate the release of ACTH and prolactin respectively (AVP has ACTH secretagogue properties in its own right[8, 9] but also acts synergistically with corticotropin-releasing factor (CRF)).

Released AVP stores are replenished within 1–2 hours. Patients with pituitary damage may achieve near normal plasma osmo-regulatory concentrations (1–8 pg/mL) of AVP via release from SON and PVN axons terminating in the median eminence. Higher plasma concentrations associated with hypovolaemia (up to 40 pg/mL) under the influence of the SNS, baroreceptor responses and A-II, cannot be achieved.

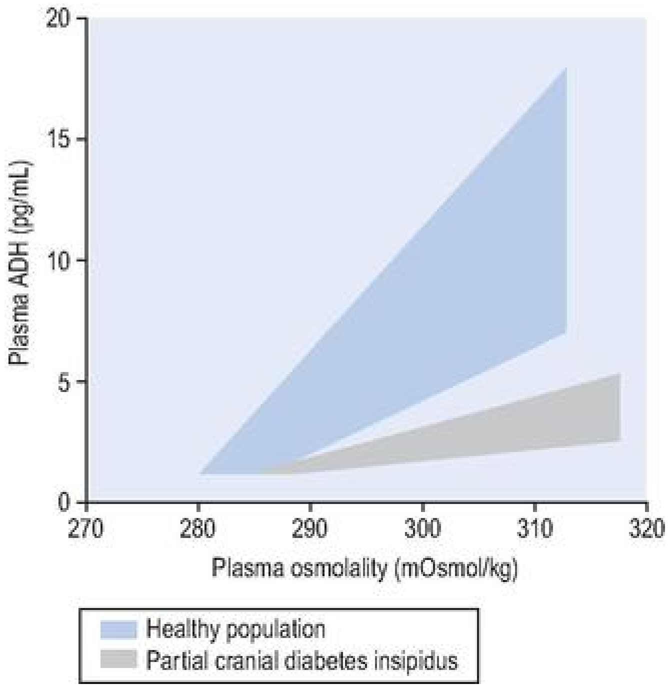
Once released, AVP has a plasma half-life of 10–35 minutes.[10] It is metabolised by hepatic, renal and placental vasopressinases with around 10% excreted unchanged in the urine. Direct measurement of plasma AVP is challenging. Copeptin has greater stability and less tendency to assay cross-reactivity and is increasingly used as a surrogate.[11]

PVN and SON inputs include:

- Osmo-(Na^+) receptors around the third ventricle sensing plasma osmolality and cerebrospinal fluid (CSF) sodium concentration.
- Sympathetic nervous system inputs via α-adrenoreceptors.
- Subfornical organ (SFO) osmoreceptors contacting plasma outside the blood–brain barrier; ANP[12] and A-II[13] are believed to act via these to inhibit or elicit ADH synthesis and/or release, and the sensation of thirst.
- Gastrointestinal osmoreceptors that pre-emptively stimulate hypothalamic ADH synthesis following ingestion of food with anticipated osmolal loads.

Baroreceptor and osmoreceptor inputs to the PVN and SON are distinct; it is possible to lose the normal AVP response to hyperosmolality but preserve it to hypovolaemia.[14] Hypotension increases basal plasma ADH concentration, causing vasoconstriction and fluid retention. Simultaneous resetting of the osmolality-plasma AVP response curve preserves osmoregulatory function from the new higher baseline,[15] preventing hypo-osmolality development in addition to vasoconstriction.

The normal response of osmoreceptors to changing plasma osmolality in terms of AVP is illustrated in Fig. 69.2 . Below 275 mOsmol/kg, the osmoreceptors remain hyperpolarised and virtually no AVP release occurs via them. Above 295 mOsmol/kg, the osmoreceptors are maximally depolarised and plasma AVP concentrations exceed 5 pg/mL. Other inputs and influences upon AVP release are summarised in Fig. 69.3 and Box 69.2 .



The graph depicts plasma antidiuretic hormone and plasma osmolality in healthy individuals and in patients with partial cranial diabetes insipidus. The horizontal axis shows plasma osmolality in millimoles per kilograms, ranging from 270 to 320. The vertical axis shows plasma A D H in picograms in millilitre, ranging from 0 to 20. Healthy population ranges from 280 millimoles per kilograms to 310 millimoles per kilograms within 0 to 15 picograms per millilitre and Partial cranial diabetes insipidus ranges from 280 millimoles per kilograms to 320 millimoles per kilograms, between 0 to 5 picograms per millilitre.

The schematic representation depicts anatomical and physiological connections of the supraoptic and paraventricular nuclei as the principal sites of antidiuretic hormone synthesis in the hypothalamus. Arrows indicate the transport of antidiuretic hormone or its precursor between distinct sites. Baroreceptor inputs travel via the vagus nerve to the central nervous system. Antidiuretic hormone produced in these nuclei is transported to the posterior pituitary for storage or to the median eminence and anterior pituitary for synergistic action on adrenocorticotropic hormone secretion. The area postrema, corticotropin-releasing factor, and subfornical organ are marked.

FIG. 69.3 A schematic representation of anatomical and physiological connections of the supraoptic and paraventricular nuclei (SON and PVN), the principal sites of antidiuretic hormone (ADH) synthesis within the hypothalamus. *Blue arrows* represent the

transport of ADH or its precursor between anatomically distinct sites. Baroreceptor inputs into these nuclei travel via the vagus nerve to reach the central nervous system. Whereas the majority of ADH produced in the SON and PVN is transported to the posterior pituitary (PP) for storage, some is transported to the median eminence (ME) and then onwards to the anterior pituitary (AP), where it acts synergistically as a secretagogue for adrenocorticotropic hormone (ACTH). *APo* , Area postrema; *CRF* , corticotropin-releasing factor; *SFO* , subfornical organ.

Box 69.2

Factors influencing antidiuretic hormone release

Increased ADH release with

- Hyperosmolality
- Hypovolaemia
- Hypotension
- Hypoxia
- Hypothyroidism
- Hyperthermia
- Positive-pressure ventilation
- Pain
- Emotional stress
- Exercise
- Nausea
- Nicotine
- Trauma/surgery

Decreased ADH release with

- Elevated ANP, BNP
- Hypo-osmolality
- Hypervolaemia
- Hypertension
- Ethanol

Cranial DI

ADH , antidiuretic hormone; *ANP* , atrial natriuretic peptide; *BNP* , brain natriuretic peptide; *DI* , diabetes insipidus.

Actions of 8-Arginine Vasopressin (AVP) (Antidiuretic Hormone (ADH))

Through V_1 , V_2 and V_3 receptors, ADH has antidiuretic, vasopressor, haemostatic and ACTH secretagogue actions and a plethora of other activities. For the purpose of this chapter, we shall consider the actions relating to volume, water and solute regulation.

Antidiuresis

AVP:

- activates V_2 receptors in collecting duct and distal tubule membranes stimulating cAMP-mediated aquaporin-2 (AQP_2) water-channel integration into the luminal membrane and water re-absorption
- stimulates collecting duct luminal membrane V_1 receptors[16] increasing prostaglandin E_2 (PGE_2) synthesis, reducing cAMP; a possible autoregulatory mechanism
- increases urea transport protein expression in the collecting duct and reduces renal medullary blood flow (V_1 -mediated), increasing medullary interstitial hypertonicity and urinary concentrating ability. Loop diuretics and Loop of Henle pathologies reduce collecting duct to interstitium osmolal gradients and AVP-mediated water absorption.

Exogenous AVP administration may paradoxically induce diuresis in patients with septic shock.[17] Increased renal perfusion pressure and thereby

GFR may be responsible. Hypokalaemia, lithium and hypercalcaemia antagonise the renal actions of AVP.

Vasoconstriction

At higher concentrations, AVP activates both V_1 and V_2 receptors, causing preferential vasoconstriction in muscle, skin and fat with possible sparing of coronary, cerebral and mesenteric circulations. [18–21]

Following brainstem death, reducing AVP may cause both hypotension and cranial diabetes insipidus (CDI) with disturbances of osmolality and organ function. α-adrenoreceptor agonists may restore organ perfusion pressure but also cause ischaemic damage. Low-dose AVP infusions (0.5–3 U/h) titrated against urine output reduce the need for catecholamine support and perturbations in plasma osmolality and fluid balance. 1-Deamino-8-O-arginine vasopressin (DDAVP) has similar benefits but causes less vasoconstriction and is preferred where hypotension is not evident.

ACTH secretion

ADH transported from the median eminence to the anterior pituitary stimulates V_3 receptors causing ACTH release, thereby increasing plasma cortisol. It also enhances CRF-mediated ACTH release. In septic shock, AVP insufficiency may contribute to the reduced ACTH and critical illness-related corticosteroid insufficiency sometimes seen.

Volume receptors

Volume homeostasis takes precedence over osmoregulation; rises and falls in sodium occur to preserve circulating volume. In euvolaemia, sodium homeostasis is preserved. Sodium concentration is detected by SFO osmoreceptors outside the blood–brain barrier and by the juxtaglomerular apparatus which secretes renin in response to both reduced GFR and reduced tubular sodium load. [22, 23]

High-pressure baroreceptors in the pulmonary veins, left atrium, carotid sinus and aortic arch are the predominant determinants of sodium balance. [24] Reduced stretch increases SNS activity, activates the RAAS, reduces sodium excretion (via reduced GFR), increases sodium re-absorption in proximal and distal convoluted tubules and stimulates AVP release, resulting in concomitant water retention. Conversely, increased stretch results in the reduction of these responses and stimulates ANP and BNP. This favours diuresis and natriuresis over sodium and volume conservation.

The basic physiology having been outlined, we shall now consider specific instances of water (diabetes insipidus, primary polydipsia) and solute diuresis, their investigation and management.

Cranial Diabetes Insipidus (CDI)

Congenital CDI

Congenital CDI is usually an autosomal dominant, inherited characteristic, resulting from genetic mutations encoding the AVP precursor pre-provasopressin neurophysin II. [25] Onset occurs between 1 and 40 years of age with progressive destruction of SON and PVN cells as abnormal precursor accumulates. [26] Until destruction is advanced, AVP secretion (facilitated by expression of the normal gene) and plasma osmolality may be unaffected.

Acquired CDI

Acquired CDI may be transient or permanent with either absolute or relative lack of AVP. Non-traumatic causes include vascular [27] and autoimmune pathologies. [28] Complete CDI is usually associated with PVN/SON or neurohypophyseal stalk lesions, with cessation of AVP production. [29] Obliterating or chronic inflammatory lesions cause permanent CDI, whereas transient CDI is associated with acute inflammation and subsequent resolution. Transient DI following posterior pituitary destruction is an exception; continued median eminence AVP release may partially compensate.

Impaired AVP response to rising plasma osmolality results in inappropriately high urine output and low urine osmolality. Absolute AVP deficiency may cause >20 L/day of dilute urine (25–200 mOsomol/kg) production. If coincident with impaired thirst or impediments to drinking, profound dehydration will follow.

With partial AVP deficiency, urinary osmolalities of 300–800 mOsmol/kg and volumes down to 3 L/day are not atypical. Nonetheless, the urine osmolality is inappropriately low and volume inappropriately high relative to minima required for the solute excretion in health. The diagnosis of partial CDI may not be obvious; there are many other causes of diuresis of this magnitude. Additionally, extrinsic stimulants of ADH release (see Box 69.2) may have an antidiuretic effect, further complicating the diagnosis.

In CDI with intact thirst, high volumes of water are ingested, maintaining water balance and relatively constant plasma osmolality at high-normal values. Hyper-osmolality or hypernatraemia may be fatal if unrecognised and untreated. They suggest either:

- impaired thirst
- restricted access to water
- administration of isotonic fluids to replace hypotonic urinary losses.

Whilst impaired AVP production accounts for most CDI, it is possible to have the normal release of AVP in response to hypotensive baroreceptor activation but subnormal release in response to hyperosmolality. This implies osmoreceptor dysfunction and may be associated with chronic hypernatraemia. [14]

The causes of CDI are listed in Box 69.3 . Transsphenoidal suprasellar tumour excision causes CDI in 10%–70% of patients, sometimes without reduction in plasma AVP; hypothalamic AVP precursors released from the operative site may act as competitive antagonists of both AVP and synthetic analogues. Such competitive antagonists create a picture mimicking nephrogenic diabetes insipidus (NDI) with normal or high plasma AVP but an inappropriate diuresis of dilute urine.

Box 69.3

Causes of cranial diabetes insipidus

Acquired

1. idiopathic
2. autoimmune [25]
3. tumours (especially suprasellar, lung, breast, lymphoma and leukaemia)
4. surgery (especially transsphenoidal surgery)
5. traumatic head injury (strongly associated with base of skull fracture) [30]
6. hypoxic brain injury
7. brainstem death
8. electrolyte disturbance – profound hyponatraemia
9. radiotherapy
10. drugs – amiodarone, lithium (Li more likely to cause nephrogenic DI)
11. inflammatory/infectious diseases
    - sickle cell disease
    - TB
    - abscesses
    - encephalitis
    - meningitis
    - sarcoidosis (may also cause nephrogenic DI)
    - Wegener's granulomatosis
    - histiocytosis X
12. vascular disease
    - ischaemic or haemorrhagic strokes
    - aneurysmal bleeds (especially anterior communicating artery SAH [subarachnoid haemorrhage])
    - Sheehan's syndrome
    - pituitary apoplexy

Congenital (1%–2% of all cases)

1. autosomal dominant mutations of ADH expression (despite the dominant expression of the gene, the onset of clinical DI may take up to 30 years to develop) [31]

2. Wolfram syndrome – autosomal recessive condition characterised by DI, diabetes mellitus, optic atrophy and deafness

ADH , antidiuretic hormone; *DI* , diabetes insipidus.

Different patterns of polyuria are described following brain injury, including trauma, surgery and haemorrhage:

(1) Immediate polyuria which may be transient (often lasting months) or permanent
(2) Transient oliguria following an initial surge of AVP followed by polyuria
(3) A triphasic pattern:
  - transient polyuria owing to impaired AVP release (0–5 days in duration) then:
  - transient normal or reduced urine output; the AVP previously stored in the involuting pituitary cells is gradually released into the circulation (3–6 days in duration)
  - persistent polyuria as the pituitary stores exhaust without further hypothalamic replacement

During the second phase of the triphasic response, fluid administration may cause volume overload and hyponatraemia as AVP release results from unregulated pituitary involution without feedback control from osmoreceptors; effectively a transient syndrome of inappropriate secretion of ADH (SIADH). Careful, regular clinical and biochemical assessments are essential to ensuring normal water balance and osmolality during this transition from DI to SIADH and back to DI again.

Regardless of the urinary pattern, unless DI resolves, regular, meticulous patient assessments, including fluid balance, hydration, plasma and urinary biochemistry, are necessary to avoid fluid and solute imbalances that worsen morbidity. Hypothalamic and pituitary T1 MRI imaging may provide prognostic information as to the likelihood of recovery; hypothalamic lesions have a poorer prognosis than pituitary ones.[32]

Elevated suspicion of DI is warranted in those with past history of pituitary disease or injury, as symptom onset may be insidious. Anterior pituitary failure (ACTH deficiency) reduces GFR and free water loss, potentially lessening the impact of CDI. Additionally, loss of feedback inhibition may increase median eminence AVP release. Thus in pituitary apoplexy, presenting symptoms may not include polyuria. Following corticosteroid replacement, GFR rises and DI may become apparent. Reciprocally, persistent idiopathic CDI merits long-term neuro-endocrine follow-up; a proportion develop pituitary tumours pituitary years after their CDI diagnosis.[33], [34]

Treatment of Cranial Diabetes Insipidus

Four separate facets require assessment and management if disordered in CDI:

1. Anterior pituitary function
2. Hypernatraemia
3. Hypovolaemia and water deficits
4. Polyuria and AVP deficiency.

In the ICU, hourly fluid balance recording and at least bi-daily urine and plasma osmolality measurements are recommended. In shocked and/or hypernatraemic patients, hourly monitoring of plasma sodium is recommended to avoid worsening hyperosmolality or over-rapid correction of hypernatraemia.

Anterior Pituitary Dysfunction

If present, this requires recognition and treatment. In a shocked patient, hydrocortisone 100 mg may be administered as an intravenous (IV) bolus, and steroid replacement continued if required. Steroids may worsen diuresis but will improve cardiovascular stability in patients with pituitary failure.

Hypernatraemia

The water diuresis of CDI tends to hypernatraemia. Fluid restriction or fluid or replacement with isotonic (to plasma) intravenous fluids in CDI with ongoing water diuresis exacerbates hyperosmolality/hypertonicity. To counteract cellular dehydration in hypernatraemic states, the brain accumulates intracellular organic osmolytes.[35-37] Sudden reduction in plasma tonicity may subsequently cause cerebral oedema, pontine myelinolysis and permanent neurological damage as water enters cells down osmotic gradients.

In euvolaemic states, AVP or DDAVP may be administered to reduce urine output (see later). Simultaneous fluid restriction and replacement of the previous hour's urine output with an appropriate fluid to avoid plasma sodium concentration falling by more than 0.5 mmol/L/h[38] and more than 8 mmol/L/day[39] is then introduced. Close monitoring of hourly plasma sodium measurement most reliably avoids sudden unexpected changes in tonicity.[40]

Correction of Hypovolaemia and Water Deficits

Hypovolaemic shock requires rapid resuscitation. If hypernatraemia is also present, extreme caution is required during resuscitation to avoid over-rapid reduction of plasma tonicity. Isotonic saline should be used alone or in combination with hypertonic saline, especially with hypernatraemia >155 mmol/L. Frequent reassessments of plasma sodium, cardiovascular and neurological states are recommended. Any suggestion of over-rapid fall in plasma tonicity with cerebral oedema should favour the use of hypertonic saline.

Correction of Polyuria and ADH Deficiency

During mild polyuria (2–3 mL/kg per hour) without hypernatraemia, where resolution is expected, replacement of the previous hour's urine output with appropriate fluid (usually 5% dextrose, 0.18% saline/4% dextrose or nasogastric water) whilst closely monitoring plasma and urinary osmolality and electrolytes may suffice. Over-administration of dextrose solutions may cause hyperglycaemia, hyperosmolality and osmotic diuresis.

Severe (>3 mL/kg/h) or persistent polyuria merit AVP or DDAVP administration. Resistant to breakdown by vasopressinases, DDAVP is long-acting, a selective V_2 receptor agonist and less likely to cause hypertension. Daily administration of 1–4 µg, in single or divided doses, by intravenous, intramuscular or subcutaneous routes or 10-40 µg intra-nasal administration is usual. AVP may be administered subcutaneously or by intravenous infusion. In the acute situation, an infusion (0.1–3 U/h) can be titrated against urine output facilitating re-establishment of the hypertonic renal medullary interstitium before conversion to longer-acting DDAVP.

The minimum doses of AVP and DDAVP necessary to achieve control of urine output should be used. Excessive administration may cause water retention and hypo-osmolal syndromes.

Higher doses may be needed during the acute onset of CDI, potentially reflecting loss of medullary interstitial hypertonicity, competitive antagonism at V_2 renal receptors by biologically inactive AVP precursors released from the damaged tissues, or both.

Other drugs may also reduce CDI-related polyuria. If residual AVP synthesis remains, chlorpropamide, clofibrate and carbamazepine are reported to enhance its release and also renal responsiveness to it. In modern ICU management, DDAVP and AVP have better efficacy, safety profiles and dose-response titration. Therefore the use of alternatives is largely confined to NDI management (see later).

Nephrogenic Diabetes Insipidus (NDI)

NDI may be congenital or acquired (Box 69.4). Congenital cases usually present in the first week of life and the majority of cases in adult ICUs are acquired. The commonest causes are toxicity secondary to long-term lithium treatment, hypercalcaemia and post-obstructive uropathy.

Box 69.4

Causes of nephrogenic diabetes insipidus

Acquired

1. lithium toxicity
2. post-obstructive diuresis
3. hypercalcaemia
4. hypokalaemia

5. hypoproteinaemia
6. Sjogren’s syndrome
7. amyloid
8. multiple myeloma
9. sickle cell disease
10. polycystic kidney disease
11. pyelonephritis
12. renal transplantation
13. other drugs: amiodarone, amphotericin B, clozapine, colchicine, demeclocycline, foscarnet, gentamicin, loop diuretics, rifampicin

Congenital

1. x-linked recessive – $AVPR_2$ gene mutations
2. autosomal recessive or dominant – AQP_2 gene mutations
3. Bartter’s syndrome
4. Gitelman’s syndrome
5. Urea Transport Protein B (Kidd Ag) deficiency/absence

Congenital NDI

Around 80%–90% of congenital NDI patients are male with x-linked recessive $AVPR_2$ gene coding abnormalities resulting in intracellular trapping of the V_2-receptor [25, 41] preventing integration into the collecting duct membrane. Drugs facilitating membrane integration, restoring some AVP-mediated urine concentrating abilities are being investigated. [42] Females presenting usually have less severe polyuria due to part-expression of the recessive gene.

Around 10% of cases of congenital NDI have mutations of the gene encoding AQP_2 channels. These are not x-linked. Over 40 autosomal dominant and recessive mutations have been described to date.

The remaining congenital NDI cases arise from pathophysiology that prevents the generation of renal medullary interstitial hypertonicity, reducing water re-absorption even with normal V_2 receptors and AQP_2 channels.

The red blood cell Kidd antigen (glycoprotein) is a urea transporter also expressed in collecting duct cells for interstitial transfer of urea from urine. Its absence reduces normal osmolal gradients and water re-absorption; urine concentrations are <800 mOsmol/kg even with water deprivation and AVP administration.[43] Similarly, patients with mutations of the chloride channel, potassium channel or sodium-potassium-chloride co-transporter genes resulting in Bartter's Syndrome cannot generate medullary interstitial hypertonicity; urine rarely concentrates >350 mOsmol/kg.[44]

Early diagnosis and management of congenital NDI is essential to avoid hypernatraemia, dehydration and cerebral damage, facilitating normal development.

Acquired NDI

Lithium-associated nephrotoxicity is the commonest cause of acquired NDI; >20% of patients on long-term therapy develop polyuria. Lithium enters collecting duct cells via sodium channels and inhibits adenylate cyclase, thereby antagonising AVP-mediated AQP_2 expression and membrane integration. It also reduces medullary interstitial hypertonicity, possibly through reducing urea transporter expression. Amiloride administration partly reverses early lithium nephrotoxicity and polyuria. Its natriuretic action occurs through closure of the collecting duct luminal sodium channels through which lithium enters the cells.[45] NSAIDs increase intracellular cAMP, counteracting lithium's actions and reducing urine output. However, they may also reduce GFR and lithium excretion, thereby worsening toxicity.

Hypercalcaemia, hypokalaemia, relief of urinary tract obstruction and hypoproteinaemia are also recognised as acquired causes of NDI. They are associated with reduced: expression of AQP_2 channels, urea transport and interstitial hypertonicity. Polyuria is usually less severe than that associated with lithium. Ageing also reduces urinary concentrating ability due to a combination of changes characteristic of both NDI and CDI with relative reductions of both AQP$_2$ and AVP production.[46]

Treatment of NDI

Management aims to remove underlying causes wherever possible and to minimise the occurrence of hypernatraemia and hypovolaemia.

1. Correct reversible causes
    a. Stop any drugs suspected in the aetiology
    b. Correct hypokalaemia, hypercalcaemia and hypoproteinaemia
2. Reduce solute load. If the maximum urine concentration is 250 mOsmol/kg, a solute intake of 750 mOsmol/day requires the production of >3L of urine to clear the solute. If intake is reduced to 500 mOsmol/day, 2L of urine will suffice. In ICU, reduction of solute intake is difficult as drugs and diluents have high solute loads and catabolic patients have high protein requirements. Rather than restricting solute intake, close monitoring of fluid balance and adequate, appropriate replacement of urinary losses may be preferred.
    a. Salt intake restriction (aiming <100 mmol/day)
    b. Reduce protein intake to meet minimum daily requirements including essential amino acids. Protein restriction in children is inappropriate and may negatively impact growth and development.
3. Diuretics – thiazides and amiloride
    a. Thiazides – In DI, water losses exceed solute ones causing plasma hyperosmolality and intracellular dehydration to maintain intravascular volume. Thiazides cause greater solute than water losses, reducing intravascular volume, GFR and ANP, and increasing SNS/RAAS activation, AVP release and collecting duct AQP$_2$ expression.[47] Proximal tubular sodium and water resorption rises, less ultrafiltrate reaches the collecting duct and a 30% reduction in urine volumes may

    result. Combined with dietary solute reduction, volumes may be reduced by up to 50%.
  - b. Amiloride use as a thiazide adjunct may further reduce urine output and combat hypokalaemia. As noted previously, in lithium nephrotoxicity, if administered early, it may both reduce cellular damage and reverse lithium antagonism of AVP.

    Loop diuretics are not effective in reducing the diuresis of NDI. Whilst reducing intravascular volume and stimulating the SNS similarly to thiazides, they also reduce interstitial medullary hypertonicity thereby reducing water re-absorption by the collecting duct rather than enhancing it.

4. AVP

   In partial NDI (most acquired cases), supplementing AVP to maintain supraphysiological concentrations may reduce urine production by up to 25% through greater V_2 receptor occupation. Long-term use may cause hypertension.

5. NSAIDs

   PGE_2 increases GFR and urine flow and decreases intracellular cAMP and AQP_2. NSAIDs reduce renal PGE_2 production and may reduce urine output up to 50%.[48] Greatest efficacy is cited for indomethacin.[49] Combination with low-solute diet and a thiazide may enhance antidiuretic benefits.[50] However, risks of renal impairment and gastric erosions are magnified in the ICU population.

6. Chlorpropamide

   This increases both AVP release and renal responsiveness to it. It also increases renal medullary hypertonicity. Doses used (250 mg od or bd) may cause hypoglycaemia[51] and use is reserved for severe refractory partial NDI.

7. Clofibrate

   This lipid-lowering agent enhances AVP release and renal sensitivity to it.[52] Its use in NDI has been associated with myopathy[53] and regular biochemical monitoring for this is advised.

8. Carbamazepine

   Although more effective in treating partial CDI, carbamazepine in doses three times those effective in epilepsy may reduce urine output in partial NDI. The high dose rate limits its utility.

9. Molecular chaperones

   Novel ‘molecular chaperones’ are being developed to treat NDI where functional V_2 receptors are confined intracellularly, unable to integrate into the principal cell basolateral membranes.[54] These membrane-permeable V_2 receptor antagonists cause receptor refolding into forms that allow membrane integration.[55] Animal models of congenital NDI, in vitro human V_2R mutations testing and early studies in humans report some successes.[56] Unfortunately, a Relcovaptan (SR49059) study, whilst showing promising clinical results, had to be discontinued owing to cytochrome P450 pathway interference. Nonetheless, other chaperone molecules are currently being explored for human testing.[57-59]

Gestational Diabetes Insipidus (GDI)

In pregnancy, possibly secondary to increased human chorionic gonadotropin,[60] the central osmostat resets,[61],[62] thirst develops at osmolalities around 10 mOsmol/kg lower and the normal range of plasma osmolality falls to 265–285 mOsmol/kg. Reduced baroreceptor stimulation stimulates the retention of water and sodium.[63]

Placental vasopressinases increase AVP metabolism up to fourfold and placental relaxin contributes to a 50% increase in GFR and venodilatation. [64] Aldosterone concentrations rise up to fivefold. Daily urinary production increases as a result of an increased solute load (including urinary proteins, glucose and amino acids), increased drinking and a raised GFR. Increased solute excretion means that small reductions in urine concentrating ability may cause large increases in urine volume. Diagnosis of GDI (see Box 69.5) requires careful differentiation from physiological polyuria and other pathological polyurias, for example, gestational diabetes.

Box 69.5

Causes of gestational diabetes insipidus

1. Sheehan’s syndrome
2. Pituitary apoplexy
3. Hepatic dysfunction:
    a. Acute fatty liver of pregnancy
    b. Pre-eclampsia
    c. HELLP syndrome
4. Vasopressinase release by placenta
5. Idiopathic gestational nephrogenic diabetes insipidus (resolves post-partum)

HELLP , haemolysis, elevated liver enzymes, low platelets.

GDI occurs in around 1:30,000 pregnancies and can result from:

1. Increased AVP destruction by **overexpressed placental vasopressinases** [65] (especially twin pregnancies) or reduced de-activation of vasopressinases (e.g. in acute fatty liver of pregnancy), [66] pre-eclampsia or haemolysis, elevated liver enzymes, low platelets (HELLP) syndrome. Exogenous AVP is also

rapidly metabolised, whereas DDAVP, the preferred treatment, is resistant to degradation by placental vasopressinase.

2. **Relative AVP insufficiency** (subclinical DI) in the non-pregnant state, maybe unmasked by increased vasopressinase activity in pregnancy. [67] Treatment with either AVP or DDAVP reduces polyuria. A proportion of these patients develop hypothalamo-pituitary axis pathologies such as tumours or hypophysitis in later life; post-partum follow-up is recommended.
3. **Pituitary apoplexy** . In pregnancy, this is usually post-partum Sheehan's syndrome preceded by bleeding or hypotension at the time of delivery. However, it may also occur antenatally [68] as a result of bleeding or infarction. Expert management of the associated spectrum of neuroendocrine deficiencies is required.
4. Gestational NDI of unknown aetiology that is resistant to both ADH and DDAVP, with resolution in the post-natal period, is also described. [69]

The treatment of GDI varies depending on the underlying cause. In all cases, prevention of hypernatraemic and hyperosmolal states is essential as these will adversely affect mother and child. If these occur, very gradual, incremental correction is required in a closely monitored environment; lowering plasma sodium by as little as 10 mmol/L/day has been associated with pontine myelinolysis. [70]

The associations between acute fatty liver of pregnancy, HELLP, pre-eclampsia and DI are well recognised, if not fully understood. Liver dysfunction may reduce clearance of placental vasopressinases, thereby increasing maternal AVP metabolism. [71], [72] The polyuria of DI may mask the hypertension and fluid overload of pre-eclampsia and HELLP, leading to delayed diagnosis, management and poorer outcomes. [73] Consideration of concealed pre-eclampsia is advised in all polyuric, gravid patients.

Primary Polydipsia (PP)

In primary or neurogenic polydipsia, excessive fluid intake results in diuresis as the body seeks to lose volume. In secondary polydipsia, dehydration (e.g. solute diuresis of DKA or diarrhoea) results in hypovolaemia and/or hyperosmolality with increased drinking to compensate (Box 69.6).

Box 69.6

Causes of primary polydipsia:

1. Psychiatric disorder or disturbance [74]
    a. obsessive-compulsive disorders
    b. schizophrenia
2. Drugs causing xerostomia [75] or drying of airways
    a. oxygen therapy,
    b. phenothiazines,
    c. anti-cholinergics
3. Hypothalamic lesions which directly disturb the thirst centre [76]
    a. sarcoidosis
    b. tuberculosis
    c. MS-associated demyelination
4. Idiopathic

In primary polydipsia, the diuresis is usually of appropriate osmolality. If ingested fluids are hypotonic, AVP secretion falls and a water diuresis occurs. If they are hypertonic, falling AVP and rising ANP levels cause solute diuresis. Excessive drinking of hypotonic fluids can cause hyponatraemia and progress to water intoxication with cerebral oedema, confusion, impaired consciousness, seizures and death. Long-term polydipsia may predispose to dysregulation of AVP secretion and CDI. [77] These are important considerations in patients presenting with reduced consciousness and polyuria; water intoxication, more usually associated with SIADH, and DI may co-exist.

Solute Diuresis

Failure to reabsorb water in DI results in polyuria. Failure to reabsorb solute results in an osmotic load in the tubules and collecting duct that opposes water absorption and may also cause polyuria.

Differentiation of solute from water diuresis is best facilitated by measuring 24-hour urinary solute excretion (normal = 600–900 mOsmol/day). Values >900 mOsmol/day indicate solute diuresis. Spot urine osmolalities >300 mOsmol/kg are suggestive but not diagnostic. In critical illness, simultaneous impairment of water re-absorption and increased solute elimination are common and total solute excretion >900 mOsmol/day via hypo-osmolal urine may be seen.

Cerebral Salt Wasting (CSW)

CSW is a diagnosis of exclusion in patients found to have hyponatraemia (<135 mmol/L), hypovolaemia, low or low-normal serum osmolality, elevated urinary sodium excretion (>40 mmol/L) and inappropriately high urine osmolality (>100 mOsmol/kg) in association with recent brain injury – most commonly subarachnoid bleed. Polyuria is common. Exclusion of neuroendocrine, renal, drug (especially diuretic), cardiac failure (raised ANP/BNP) and malignant causes should precede CSW diagnosis.

The pathophysiological mechanisms underlying CSW are not well characterised. Theoretical mechanisms proposed include:

- hypothalamic injury resulting in inability to promote activation of the RAAS system in response to hyponatraemia
- release of BNP from the injured brain resulting in reductions of both renin release and tubular sodium resorption

Treatment

CSW requires the management of both volume and sodium deficits. When plasma sodium is <126 mmol/L, especially where this has been persistent for over 24 hours, caution is necessary to avoid over-rapid correction and secondary pontine myelinolysis; <10 mmol/L/day and <1mmol/L every 3 hours.

Correction of water and sodium deficits in CSW usually involves the administration of isotonic saline solution to treat total body water deficit whilst still avoiding an overly rapid rise in plasma sodium concentrations. The use of too much free water (including dextrose 5% as a drug diluent) may contribute to the development of cerebral oedema during rehydration worsening brain injury. High-frequency monitoring of plasma sodium, fluid balance, volume status, GCS and neurological function is required; fluid type and administration rate should be adapted in response to findings.

Mild CSW may be difficult to differentiate from mild SIADH, but it is important to do so as the treatments are opposite (in SIADH total body water overload and hyponatraemia are evidenced and generally managed by fluid restriction, not supplementation).

Treatment of CSW usually lasts weeks to months following the patient’s discharge from the hospital. Salt tablets, maintained fluid ingestion and fludrocortisone may all be used. Expert supervision of drug changes that may exacerbate the condition and regular monitoring of plasma sodium, renal function and hydration state is advised. Most cases are reported to resolve over time.

Polyuria During Recovering Acute Kidney Injury

Acute kidney injury in the ICU may result from pre-renal (ischaemic-hypoperfusion injury), renal (usually toxin (drug), inflammatory or microvascular circulatory disturbances) or post-renal (obstructive) injuries. In the former two categories, cellular injury, especially loss of proximal tubular brush border and epithelial sloughing usually leads to oligo-anuria. During recovery phases, tubular epithelial regeneration is a gradual process and regulation of both water and solute retention are impaired; normal concentrating and ion exchange mechanisms often lag behind the increased production of glomerular filtrate. The use of diuretics to promote diuresis can further complicate matters. During this period, fluid, protein and electrolyte losses are unpredictable. Careful monitoring and replacement are required to avoid the development of electrolyte, fluid and acid-base imbalances.

The Diagnosis of Polyuric Syndromes

Measurement of Plasma and Urine Osmolality – Water Versus Solute Diuresis

High urine osmolality in the presence of high plasma osmolality is appropriate. When plasma osmolalities are >295 mOsmol/L, urine osmolalities should reach 1000–1200 mOsmol/kg; values <300 mOsmol/kg imply DI whilst those 300–1000 mOsmol/kg should prompt consideration of causes of partial DI or reduced renal interstitial hypertonicity (e.g. loop diuretics).

Polyuria with high plasma osmolalities and urine osmolalities >1000 mOsmol/kg indicate an osmotic/solute diuresis. This may be inappropriate in that it tends to dehydration but appropriate in that the kidneys are maximally retaining water whilst maximally excreting solute. An osmolal gap >10 mOsmol/kg should prompt testing for unmeasured solutes.

Plasma osmolalities <280 mOsmol/kg imply water overload and urine osmolalities should be <50 mOsmol/kg as the body undertakes free water clearance. Low plasma osmolality with high urine osmolality implies SIADH and is not normally associated with polyuria. Consider cerebral/renal salt wasting if plasma osmolality and sodium are low/low-normal, volume depletion is present, there is a diuresis and urinary sodium is >40 mmol/L. Urine may be iso-, hyper- or hypo-osmolal to plasma.

Water Deprivation, AVP and Copeptin Tests – Differentiating PP and DI Subtypes

In health, water deprivation rapidly increases plasma osmolality, AVP, copeptin and urine osmolality rises to 1000–1200 mOsmol/kg to preserve water and restore normal plasma osmolality. Water deprivation testing (WDT) may be useful to determine the cause of persistent polyuria of unknown aetiology (see Table 69.1). Testing is potentially dangerous; dehydration and hyperosmolality may develop rapidly risking permanent cerebral damage and cardiovascular collapse. It requires close, expert supervision and should only commence in well-hydrated patients who are not hypernatraemic at baseline.

Table 69.1

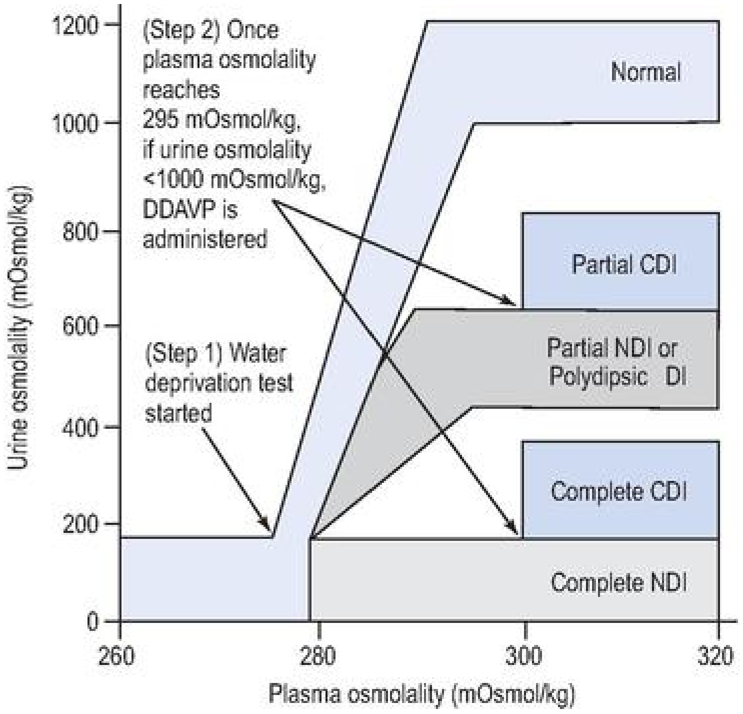
The limitations of WDT should be appreciated:

- AVP instability in blood samples and assay variability tend to measurement imprecision
- precursors from the injured brain may falsely elevate AVP measurements in acute CDI
- at high AVP concentrations, urine osmolalities in partial NDI and PP may be similar
- partial CDI patients occasionally exhibit hypersensitivity and maximally concentrate urine with small AVP rises during WDT. Misdiagnosis of PP[78] may result.
- in patients with chronic hypernatraemia and CDI secondary to osmoreceptor dysfunction, WDT-induced hypovolaemia may cause baroreceptor-mediated AVP release, suggesting normal urine concentrating abilities.[79]

Some limitations may reduce if copeptin rather than AVP is measured.[80, 81] Diagnostic accuracy may further increase using arginine infusion rather than hypertonic saline.[82]

Interpretation of the Tests (see Figs. 69.4 and 69.5)

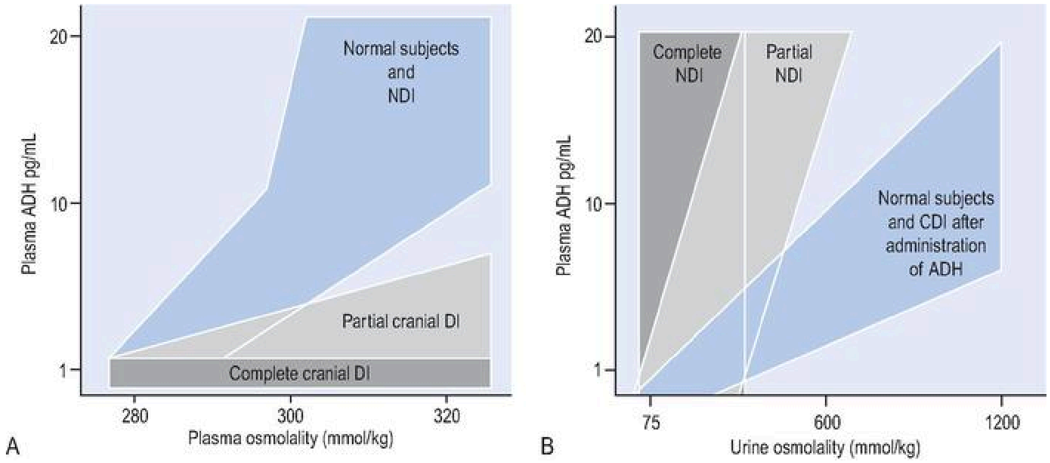
Treatment of the fluid deficit and/or hyperosmolality should precede further investigations.



The graph contains multiple lines comparing plasma vasopressin levels across osmolarity ranges. The horizontal axis shows plasma osmolarity in milliosmoles per kilogram from two hundred sixty to three hundred ten. The vertical axis presents vasopressin levels in picograms per millilitre from zero to twenty. Several sloped lines correspond to time after water restriction and different test results. Shaded zones indicate categories including normal, partial central diabetes insipidus, partial nephrogenic diabetes insipidus, complete central diabetes insipidus, and complete nephrogenic diabetes insipidus. Each shaded region covers a specific portion of the graph. Axes are marked with numeric intervals and all regions are labelled.

FIG. 69.4 Urine versus plasma osmolality during water deprivation testing. *CDI* , Cranial diabetes insipidus; *DDAVP* , 1-deamino-8-0-

arginine vasopressin; *NDI* , nephrogenic diabetes insipidus. (Adapted from Sands JM, Bichet DG. Nephrogenic diabetes insipidus. *Ann Intern Med.* 2006;144:186–189.)



The two graphs, labelled A and B, compare plasma vasopressin with plasma and urine osmolarity. The two line graphs compare hormone response in different groups. Panel A plots plasma vasopressin against plasma osmolarity. Panel B plots plasma vasopressin against urine osmolarity. Both horizontal axes represent osmolarity from low to high ranges. Vertical axes display plasma vasopressin levels in picograms per millilitre. Multiple shaded regions mark data from normal subjects, partial nephrogenic diabetes insipidus, and complete nephrogenic diabetes insipidus. Arrows or markers indicate subjects after fluid deprivation. Both panels include overlapping shaded zones. Numeric labels and group tags are provided within each panel. Line slopes vary depending on the condition.

FIG. 69.5 (A) As plasma osmolality increases as a result of water deprivation or hypertonic saline infusion, the measured concentration of antidiuretic hormone (ADH) should rise. Failure to do so suggests cranial diabetes insipidus. (B) At a given value of plasma ADH, whether endogenous or exogenous in origin, urine osmolality is expected to lie within a corresponding range of osmolality. However, the range of expected osmolalities is high as osmoreceptors adjust regulation around the basal level of ADH, which is also partly determined by volume receptors. In nephrogenic diabetes insipidus (NDI), the urine osmolality remains low even when high plasma ADH concentrations are measured. *CDI* , Cranial diabetes insipidus.

Hypertonic Saline Infusion Testing (HSIT)

Where WDTs are equivocal or dehydration/hypovolaemia risks from WDT preclude use (e.g. infants), HSIT may be undertaken. Interpretation is as for WDT with the improved demarcation between partial CDI and PP and reduced risk of missing osmoreceptor dysfunction associated CDI. [83]

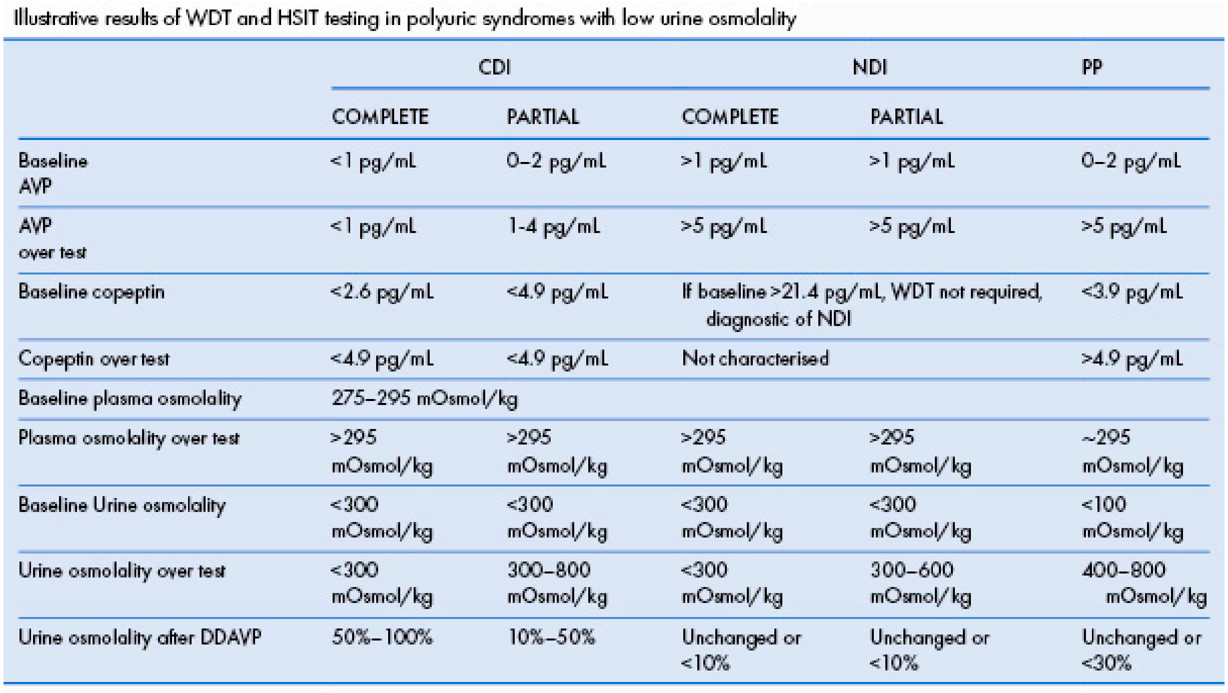
The infusion rate (mL/h) varies with the concentration of the hypertonic preparation used. 0.0425 mmol/kg/min is administered for up to 3 hours. Plasma osmolality >300 mOsmol/kg requires earlier cessation.

Blood sampling for sodium, AVP, copeptin and osmolality measurement occurs at 30-minute intervals prior to and throughout HSIT. Urine samples are collected before and ideally hourly throughout testing, for osmolality and sodium measurement. Thirst and blood pressure are recorded at 30-minute intervals.

Interpretation of the WDT and HSIT Results (Figs. 69.4 and 69.5 and Table 69.2)

Conduct and interpretation of investigative tests in polyuric ICU patients can be complex. Collaboration with endocrinologists and nephrologists is advised where polyuria and diagnostic uncertainty persist. Local testing regimes, units of measurement and value ranges may differ, those in Figs. 69.4 and 69.5 and Table 69.2 are indicative, not definitive.

Table 69.2



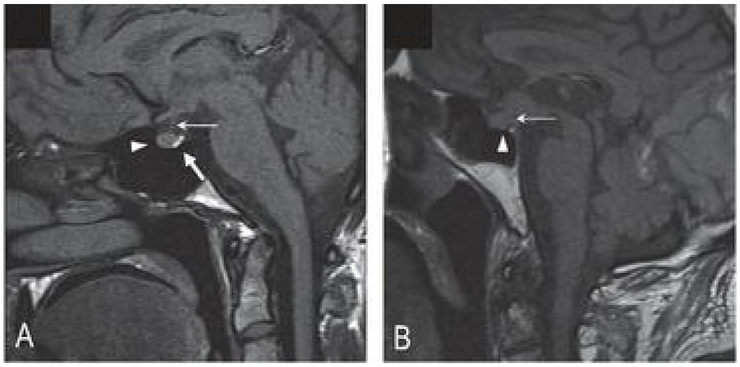
Illustrative results of WDT and HSIT testing in polyuric syndromes with low urine osmolality

	CDI		NDI		PP
	COMPLETE	PARTIAL	COMPLETE	PARTIAL	
Baseline AVP	<1 pg/mL	0–2 pg/mL	>1 pg/mL	>1 pg/mL	0–2 pg/mL
AVP over test	<1 pg/mL	1-4 pg/mL	>5 pg/mL	>5 pg/mL	>5 pg/mL
Baseline copeptin	<2.6 pg/mL	<4.9 pg/mL	If baseline >21.4 pg/mL, WDT not required, diagnostic of NDI		<3.9 pg/mL
Copeptin over test	<4.9 pg/mL	<4.9 pg/mL	Not characterised		>4.9 pg/mL
Baseline plasma osmolality	275–295 mOsmol/kg				
Plasma osmolality over test	>295 mOsmol/kg	>295 mOsmol/kg	>295 mOsmol/kg	>295 mOsmol/kg	~295 mOsmol/kg
Baseline Urine osmolality	<300 mOsmol/kg	<300 mOsmol/kg	<300 mOsmol/kg	<300 mOsmol/kg	<100 mOsmol/kg
Urine osmolality over test	<300 mOsmol/kg	300–800 mOsmol/kg	<300 mOsmol/kg	300–600 mOsmol/kg	400–800 mOsmol/kg
Urine osmolality after DDAVP	50%–100%	10%–50%	Unchanged or <10%	Unchanged or <10%	Unchanged or <30%

Local testing protocols, expertise and reference ranges for results should always be used.

Magnetic Resonance Imaging T1-Weighted Imaging of the Neurohypophyseal Tract

Imaging may assist in differentiating partial CDI from PP where doubt persists following WDT and copeptin measurement is unavailable. The normal bright spot (stored AVP) in the posterior pituitary is usually reduced or absent in CDI, but present or enhanced in PP (Fig. 69.6). This is insufficiently specific or sensitive for use in isolation; the signal may also reduce in NDI and up to 30% of elderly subjects without DI symptomatology. Additionally, the signal intensity may change bi-directionally over time, even in young subjects.



The two sagittal T 1-weighted magnetic resonance imaging scans depict the hypothalamic pituitary region in two patients. The first scan depicts a normal anterior pituitary, pituitary stalk, and hyperintensity of the posterior pituitary. The second scan depicts a patient with cranial diabetes insipidus showing a thickened pituitary stalk and absent hyperintense signal in the posterior pituitary gland.

FIG. 69.6 Sagittal T1-weighted magnetic resonance imaging scans of the hypothalamic-pituitary region in a patient with posterior pituitary (A) and a patient with cranial diabetes insipidus (CDI) (B). (A) A normal anterior pituitary *(arrowhead)* and pituitary stalk *(thin white arrow)* and hyperintensity of the posterior pituitary *(thick white arrow)* . (B) Sagittal T1-weighted scan obtained in a patient with CDI due to lymphoma shows a massively thickened pituitary stalk *(thin white arrow)* and an absent hyperintense signal in the posterior pituitary gland *(arrowhead)* . Thyroid emergencies

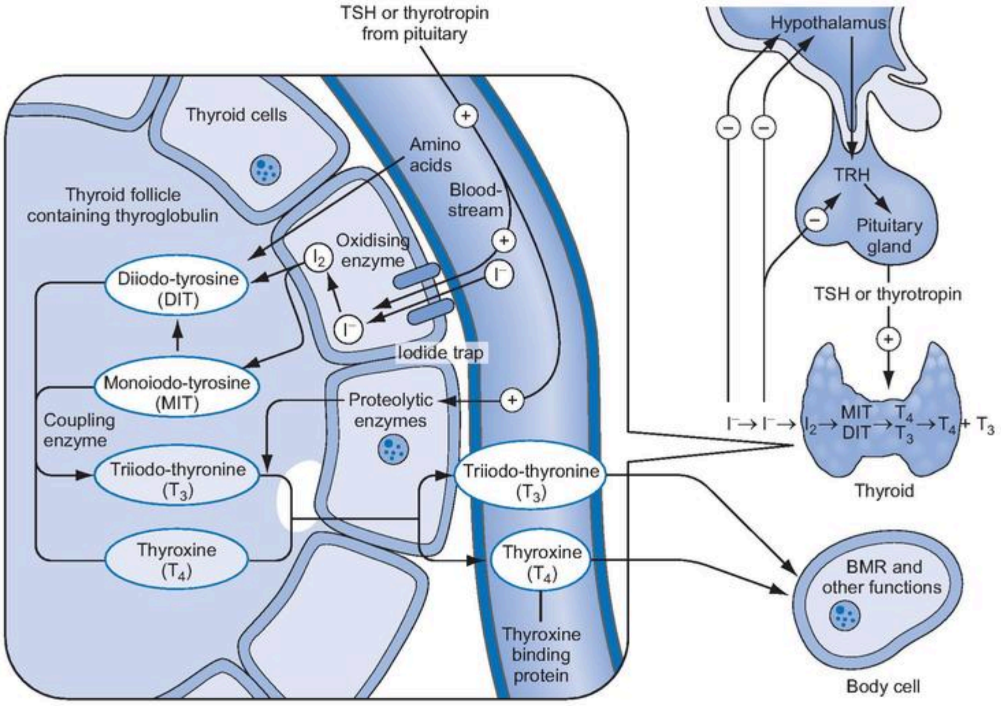
Alex Li and Jonathan M. Handy

Introduction

Thyroid emergencies are a rare cause for admission to critical care. However, mortality is high unless specific treatment is provided in an expeditious manner. Abnormal thyroid function tests (TFTs) are commonly encountered during critical illness; numerous factors must be considered before interpreting these findings as indicating thyroid disease.

Basic Physiology

Thyroid hormones affect the function of virtually every organ system and must be constantly available for these functions to continue. The two biologically active hormones are tetraiodothyronine (thyroxine or T_4) and triiodothyronine (T_3). These are synthesised by incorporating iodine into tyrosine residues, a process which occurs in thyroglobulin contained within the lumena of the thyroid gland (Fig. 70.1). Stimulation of hormone release by thyroid-stimulating hormone (TSH) results in endocytosis of thyroglobulin from the lumen into the follicular cells, followed by hydrolysis to form T_4 and T_3, which is released into the circulation.[1]



TSH or thyrotropin from pituitary
Thyroid cells
Amino acids

BMR and other functions
Body cell

The schematic representation illustrates thyroid hormone synthesis and regulation through interconnected pathways. On the left, a cross-sectional view of thyroid follicle cells displays entry of amino acids and iodide from the blood. Arrows lead to steps involving oxidising enzymes, iodination of tyrosine, and formation of monoiodotyrosine and diiodotyrosine. These combine into triiodothyronine and tetraiodothyronine within thyroglobulin. Arrows continue to proteolytic enzyme action and release of hormones into the blood. On the right, a hormonal control axis links the hypothalamus, pituitary gland, and thyroid gland through thyrotropin-releasing hormone and thyroid-stimulating hormone. Additional arrows extend to body cells, indicating metabolic and functional effects of the hormones. All steps and structures are clearly labelled.

FIG. 70.1 Synthesis of tetraiodothyronine (T_4) and triiodothyronine (T_3). Stimulation of hormone release by thyroid-stimulating hormone (TSH) produced in the pituitary gland results in endocytosis of thyroglobulin from the lumen into the follicular cells, followed by hydrolysis to form T_4 and T_3 which is released into the circulation. *BMR*, Basal metabolic rate; *TRF*, thyrotropin-releasing factor; *TRH*, thyrotropin-releasing hormone.

Both T_4 and T_3 contain two iodine atoms on their inner (tyrosine) ring. They differ in that T_4 contains two further iodine atoms on its outer (phenol) ring, whereas T_3 contains only one, resulting in a comparatively longer plasma half-life for T_4 of 5–7 days compared with that of 10 hours for T_3. T_4 is produced solely by the thyroid gland, whereas the majority of T_3 is synthesised peripherally by the removal of one iodine atom (de-iodination) from the outer ring of T_4. If de-iodination of an inner ring iodine atom occurs, the metabolically inert reverse-T_3 (rT_3) is formed. This is produced in preference to T_3 during starvation and many non-thyroidal illnesses, and the ratio of inactive (rT_3) to active T_3 synthesis appears to play an important role in the control of metabolism.[2] Numerous factors can affect the peripheral de-iodination process (Box 70.1). Both T_4 and T_3 are highly protein bound in the serum, predominantly to thyroid-binding globulin but to a lesser extent to albumin and pre-albumin. Changes in the concentration of these serum-binding proteins have a large effect on total T_4 and T_3 serum concentrations. Such protein changes do not, however, affect the concentration of free hormone or their rates of metabolism. The serum-binding proteins act as both a store and a buffer to allow an immediate supply of the metabolically active free-T_4 (fT_4) and free-T_3 (fT_3). In addition, protein binding reduces the glomerular filtration and renal excretion of the hormones.

Box 70.1

States associated with decreased de-iodination of T_4 to T_3

- Systemic illness
- Fasting
- Malnutrition
- Postoperative state
- Trauma
- Drugs: propylthiouracil, glucocorticoids, propranolol, amiodarone
- Radiographic contrast agents (ipodate, iopanoate)

On reaching the target organs, fT_4 and fT_3 enter the cells predominantly by diffusion. Here, microsomal enzymes de-iodinate the fT_4 to form fT_3. This varies in differing tissues, the majority occurring in the liver, kidneys and muscles. The fT_3 subsequently diffuses into the nucleus, where it binds nuclear receptors and exerts its effect through stimulation of messenger RNA with subsequent synthesis of polypeptides including hormones and enzymes. The role of thyroid hormones in development and homeostasis is widespread and profound: the most obvious effects are to stimulate basal metabolic rate and sensitivity of the cardiovascular and nervous systems to catecholamines.

The regulation of thyroid function is predominantly determined by three main mechanisms, the latter two providing physiological control. Firstly, the availability of iodine is crucial for the synthesis of the thyroid hormones. Dietary iodide is absorbed and rapidly distributed in the extracellular fluid, which also contains iodide released from the thyroid gland and from peripheral de-iodination processes. This becomes trapped within thyroid follicular cells, from which it is actively transported into the lumen to be oxidised into iodine and subsequently combined with tyrosine.[3] Other ions such as perchlorate and pertechnetate share this follicular cell active transport mechanism and thus act as competitive inhibitors for the process.

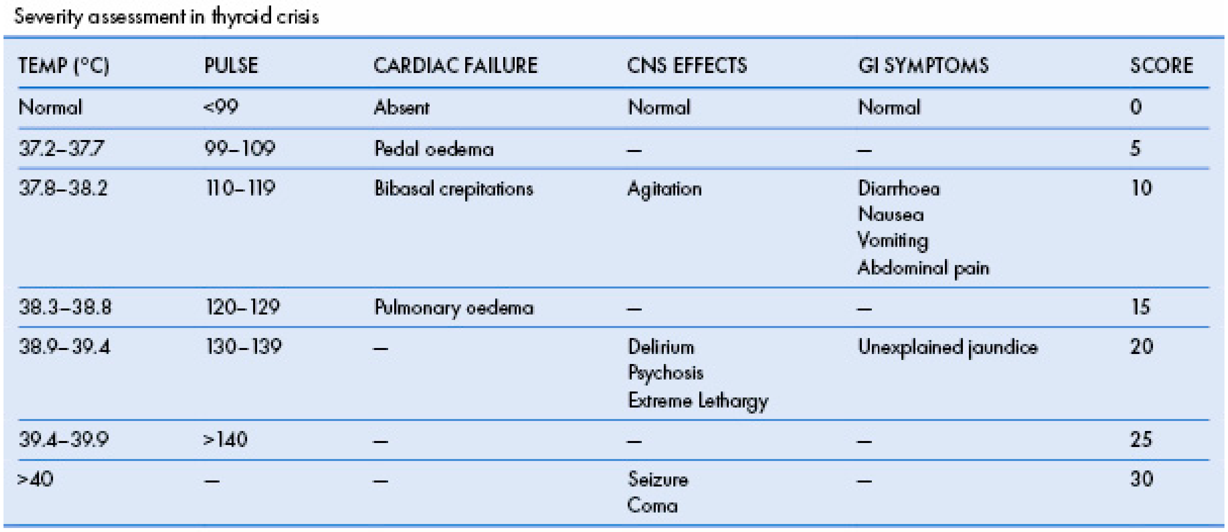
Secondly, thyroid hormone release is controlled by a close feedback loop with the anterior pituitary. Diminished levels of circulating hormones trigger the secretion of TSH, which acts on the follicular cells of the thyroid gland causing them to release thyroglobulin-rich colloid from the lumen. This thyroglobulin is hydrolysed to form T_4 and T_3 for systemic release. Increased levels of T_4 and T_3 cause diminished TSH secretion, resulting in the follicular cells becoming flat and allowing increased capacity for colloid storage. As a result, less thyroglobulin is mobilised and hydrolysed with less T_4 and T_3 release. The degree to which TSH is secreted in response to changes in circulating thyroid hormones is dependent on the hypothalamic hormone thyrotropin-releasing hormone (TRH), which is itself modulated by feedback from the thyroid hormones (see Fig. 70.1). TRH secretion is inhibited by dopamine, glucocorticoids and somatostatin.

Lastly, further regulation occurs during the enzyme-dependent peripheral conversion of fT_4 to fT_3 . It is this latter stage that provides the rapid and fine control of local fT_3 availability. All of these mechanisms may be altered by drugs and in pathological states.

Thyroid Crisis (Thyroid Storm)

Thyrotoxic storm is arguably the most serious complication of hyperthyroidism with an incidence of between 0.57 and 5.6 per 100,000 hospitalised patients per year worldwide [4-6] and reported mortality ranging from 10% to 30% in those that are hospitalised. [4,6-10] Crisis most commonly occurs as a result of unrecognised or poorly controlled Grave’s disease; however, other underlying diseases may be the cause. [10,11] Females outnumber males. Laboratory findings are inconsistent due to acute disruption of the normal steady state of the circulating hormones and there is no definitive value that separates thyrotoxicosis from thyroid storm. The latter is a clinical diagnosis and a scoring system has been proposed to guide the likelihood of the diagnosis (Table 70.1). [12] Precipitating factors are not always present, though many have been identified (Box 70.2).

Table 70.1



Severity assessment in thyroid crisis

TEMP (°C)	PULSE	CARDIAC FAILURE	CNS EFFECTS	GI SYMPTOMS	SCORE
Normal	<99	Absent	Normal	Normal	0
37.2–37.7	99–109	Pedal oedema	–	–	5
37.8–38.2	110–119	Bibasal crepitations	Agitation	Diarrhoea Nausea Vomiting Abdominal pain	10
38.3–38.8	120–129	Pulmonary oedema	–	–	15
38.9–39.4	130–139	–	Delirium Psychosis Extreme Lethargy	Unexplained jaundice	20
39.4–39.9	>140	–	–	–	25
>40	–	–	Seizure Coma	–	30

Calculations:

- Add the scores for each of the five clinically observed parameters
- Add a further **10 points** if **atrial fibrillation** is present
- Add a further **10 points** if an identifiable **precipitating factor** is present
- Total score of **45** or greater is highly suggestive of thyroid storm
- Total score of **25–44** supports impending crisis
- Total score of less than **25** makes thyroid storm unlikely

CNS , Central nervous system; *GI* , gastrointestinal.

Box 70.2

Factors associated with precipitating thyroid storm

- Infection, sepsis

- Withdrawal of antithyroid treatment
- Surgery, trauma
- Parturition
- Diabetic ketoacidosis
- Medications (radioactive iodine therapy, iodinated contrast dyes, drugs, e.g., amiodarone and thyroxine)
- Hypoglycaemia
- Excessive palpation of the thyroid gland
- Emotional stress
- Burn injury
- Pulmonary thromboembolism
- Cerebrovascular accident; seizure disorder (including eclampsia)

Clinical Presentation

The classic signs of thyroid crisis include hyperpyrexia, tachycardia, tremor, diarrhoea, nausea and vomiting (Box 70.3).[13] However, presentation is extremely variable and may range from apathetic hyperthyroidism (apathy, depression, hyporeflexia and myopathy)[14] to multiple organ dysfunction.[15,16] Differential diagnosis includes sepsis and other causes of hyperpyrexia such as adrenergic and anticholinergic syndromes.

Box 70.3

Clinical features of hyperthyroidism/thyroid crisis

- Hyperpyrexia
- Cardiovascular
  - Tachycardia, atrial fibrillation, ventricular arrhythmias
  - Heart failure
  - Hypertension (early), hypotension (late)

- Neuromuscular
  - Tremor
  - Encephalopathy, coma
  - Weakness
- Gastrointestinal
  - Diarrhoea, nausea and vomiting
- Respiratory
  - Dyspnoea
  - Increased oxygen consumption and carbon dioxide production
- Goitre (possible airway compromise)
- Laboratory abnormalities

Hyperpyrexia

This is the most characteristic feature. Temperature may rise above 41°C. There have been suggestions that hyperpyrexia is present in all cases of thyroid storm, [17] although normothermia has been reported. [15] Hyperpyrexia is rare in uncomplicated thyrotoxicosis and should always raise suspicion of thyroid storm. It is not clear whether this febrile response is due to alteration of central thermoregulation, or elevation of basal metabolic thermogenesis beyond the body's ability to lose heat.

Cardiovascular Features

Cardiovascular symptoms in many patients include tachycardia to rates that can exceed 140 beats/minute, atrial fibrillation (AF) and congestive heart failure. Dehydration with electrolyte imbalance is common and fluid requirements may be substantial in some patients; conversely, diuresis may be required in those with severe cardiac congestion. Cardiac decompensation can occur in young patients with no known antecedent cardiac disease. Systolic hypertension with widened pulse pressure is common initially; however, hypotension may supervene later. Shock with vascular collapse is a pre-terminal sign. [18]

Neuromuscular Features

Tremor and hyperreflexia are common early signs, but as ‘storm’ progresses central nervous dysfunction evolves with progression from agitation and anxiety to encephalopathy or even coma. [19] Thyroid storm has been reported in association with status epilepticus and cerebrovascular accident. [20] Weakness may be a feature, particularly with apathetic thyrotoxicosis. [15] Thyrotoxic myopathy and rhabdomyolysis may be present [15], [21]; the latter being differentiated from the former by its association with markedly elevated creatine phosphokinase levels. A number of other syndromes of neuromuscular weakness have been described including hypokalaemic periodic paralysis [22], [23] and myasthaenia gravis. [24]

Gastrointestinal Features

Diarrhoea, nausea and vomiting are common, though the patient may present with symptoms of an acute abdomen. [25] Severe abdominal tenderness should raise the possibility of an abdominal emergency. Liver function tests may be abnormal due to congestion or necrosis and tenderness over the hepatic area may be present. Hepatosplenomegaly may be present. The presence of jaundice is a poor prognostic sign. [18]

Respiratory Considerations

Dyspnoea at rest or on exertion may be present for a number of reasons. Oxygen consumption and carbon dioxide production are increased with subsequent increase in the respiratory burden. This may be exacerbated by pulmonary oedema, respiratory muscle weakness and tracheal obstruction from enlarged goitre (rare).

Laboratory Findings

Numerous abnormalities may be found:

- fT_4 and fT_3 are usually increased, though this does not correlate with clinical severity: TSH is often undetectable
- Hyperglycaemia in non-diabetics
- Leucocytosis with a left shift, even in the absence of infection (leucopenia may be present in patients with Grave’s disease)

- Abnormal liver function tests and hyperbilirubinaemia
- Hypercalcaemia due to haemoconcentration and the effect of thyroid hormones on bone resorption
- Hypokalaemia and hypomagnesaemia (particularly in apathetic thyrotoxicosis)
- Serum cortisol should be elevated. If low values are found, adrenal insufficiency should be considered and treated Adrenal reserve in thyrotoxic patients is often exceeded in the absence of absolute adrenal insufficiency

Management

Patients with thyroid storm or an impending crisis should be treated in the intensive care or high-dependency unit. This permits close monitoring and treatment of cardiac and neurological dysfunction and correction of accompanying dehydration and electrolyte imbalances.

Treatment is aimed at:

- Control and relief of adrenergic symptoms (B-blockers, digoxin)
- Correction of thyroid hormone abnormalities (thionamides, iodine)
- Resolving the precipitating cause
- Investigation and treatment of the underlying thyroid disease
- Supportive measures

β-Adrenergic Blockade

This is the mainstay of controlling adrenergic symptoms. However, although control of tachycardia may lead to improvement in cardiac function (if increased heart rate is the predominant cause), beta-blockers are contra-indicated in patients with acute decompensated heart failure with systolic dysfunction. In these circumstances, a beta-blockade-induced reduction in heart rate could lead to profound hypotension. [26] Intravenous propranolol titrated in 0.5–1 mg increments while monitoring cardiovascular response diminishes the systemic hypersensitivity to catecholamines. In addition, it inhibits peripheral conversion of T_4 to T_3. [27] Concurrent administration of enteral propranolol is the norm, with doses as high as 60–120 mg 4–6 hourly often being necessary due to enhanced elimination during thyroid crisis.[28] An alternative regimen uses intravenous esmolol with a loading dose of 250–500 μg/kg followed by infusion at 50–100 μg/kg per minute. This allows rapid titration of β-blockade to heart rate while minimising adverse reactions.[29]

Digoxin

Control of heart rate and rhythm may result in significant improvement in cardiac performance. Electrolyte imbalance, particularly hypokalaemia and hypomagnesaemia, should be corrected prior to drug therapy. Relative resistance to digoxin may occur due to increased renal clearance[30] and increased Na/K ATPase units in cardiac muscle.[31] Arterial thromboembolic phenomena are common (10%–40%) in thyrotoxicosis-related AF. This may be due to a procoagulant state, or an increased incidence of mitral valve prolapse. Anticoagulation is controversial, given the increased sensitivity to warfarin and the potential for bleeding; however, it should be considered in the management of these patients.

Thionamides

These drugs block de novo synthesis of thyroid hormones within 1–2 hours of administration, but have no effect on the release of preformed glandular stores of thyroid hormones. Transient leucopenia is common (20%) and agranulocytosis can rarely occur with carbimazole use.

Propylthiouracil

This is usually considered the drug of choice in thyroid storm due to its ability to partially block peripheral conversion of T_4 to T_3. Its main mechanism of action is to block the iodination of tyrosine. Only enteral preparations are available and absorption may be unpredictable during thyroid crisis. Rectal administration has been reported. The initial dose is 200 mg to 250 mg every 4 hours.

Methimazole

Methimazole lacks peripheral effects but has a long duration of action making administration easier and more reliable. It may be used in combination with drugs that block peripheral T_4-to-T_3 conversion (such as iopanoate or ipodate). Only enteral preparations are available, though rectal administration has been reported. The initial dose is 20 mg every 4 to 6 hours. A recent retrospective study comparing propylthiouracil and methimazole administration in the context of thyroid storm showed no significant differences between the two agents in mortality or adverse events.[32]

Carbimazole

This is metabolised to methimazole and is rarely associated with agranulocytosis. The initial dose for thyroid storm is 20–30 mg every 4–6 hours; only enteral preparations are available.

Iodine

The release of preformed glandular thyroid hormones is inhibited by administering either inorganic iodine or lithium. Enterally administered iodides include Lugol's solution and sodium or potassium iodide. Intravenous infusion of sterile sodium iodide may be used at a dose of 1 g 12 hourly; however, this is not always available commercially. If not, it may be prepared by the hospital pharmacy. Iodine therapy should not commence without prior thionamide administration. Used alone, it will enrich hormone stores within the thyroid gland and exacerbate thyrotoxicosis.

Iodine-containing contrast media (e.g. ipodate and iopanoate) may be used instead of the simple iodides, the former blocking T_4-to-T_3 conversion and inhibiting the cardiac effects of thyroxine. Ipodate is administered orally as a loading dose of 3 g followed by 1 g daily. As with the iodides, treatment should always be preceded by thionamide administration.

Amiodarone

Amiodarone has theoretical benefits in thyrotoxicosis as it inhibits peripheral conversion of T_4 to T_3 and reduces the concentration of T_3-induced adrenoceptors in cardiac myocytes.[33] It does, however, cause profound (though sometimes physiologically irrelevant) changes to TFTs, and it can itself trigger thyrotoxicosis. It should not, therefore be used as a first-line agent in the management of AF associated with thyrotoxicosis; if rhythm control is desired, then alternative agents should be used in preference.

Lithium

Lithium carbonate has a similar, though weaker action to iodine and can be used in patients with iodine allergy. An initial dose regime of 300 mg 8-hourly has been used with subsequent dosage adjusted to maintain serum drug levels at about 1 mmol/L. [34] Renal and neurological toxicity tend to limit its use.

Steroids

Glucocorticoids reduce T_4-to-T_3 conversion and may modulate any autoimmune process underlying the thyroid crisis (e.g. Grave’s disease). In addition, relative glucocorticoid deficiency may be a feature of the crisis. An adrenocorticotropic hormone (ACTH) stimulation test is desirable prior to administration of hydrocortisone (100 mg 6–8-hourly); alternatively, dexamethasone (4 mg 6-hourly) can be administered until the test has been performed. Combination therapy with iodides can produce rapid results. Glucocorticoids are the most effective treatment for type-2 amiodarone-induced thyrotoxicosis. [35]

Other Therapies

Plasmapheresis, charcoal haemoperfusion and dantrolene have all been used as novel therapies in thyroid storm; however, their use is not established or proven. Where patients are unable to continue thionamides due to side effects (such as allergy, agranulocytosis or hepatotoxicity), surgical thyroidectomy is the treatment of choice.

Supportive Therapy

Fluid management

Fluid management may be extremely difficult in patients suffering from thyroid storm, particularly the elderly. Fluid losses may be profound due to diarrhoea, vomiting, pyrexia and reduced intake. However, congestive cardiac failure may also develop as a result of the high cardiac demand. Echocardiography and cardiac output monitoring may be invaluable in guiding therapy for such patients.

Temperature control

Usually, this can be achieved via passive cooling, but refractory hyperpyrexia has been successively treated with active measures such as endovascular cooling. [36]

Nutrition

Thyrotoxic patients have high energy expenditure and may present with a significant energy, vitamin and nitrogen deficit. Nutritional requirements should take account of any deficit and the ongoing hypercatabolic state. Thiamine is usually supplemented.

Drug therapy

Consideration should be given to the enhanced metabolism and elimination of drugs that occur in thyrotoxic patients. Salicylates and furosemide should be avoided, as they both displace thyroid hormones from their binding proteins and can rapidly exacerbate systemic symptoms.

Precipitating factors

Both the precipitating factors and the disease process underlying the thyroid crisis should be sought and treated aggressively. Infection is the leading precipitant of crisis; thus early microbiological cultures and antibiotic therapy should be considered.

Myxoedema Coma

Myxoedema coma is the extreme manifestation of hypothyroidism which, although rare, carries a mortality of approximately 30%. [37] The term is a misnomer in that the majority of patients present with neither non-pitting oedema known as myxoedema nor coma. [38] The condition should be considered in any patient presenting with a reduced level of consciousness and hypothermia. The crisis occurs most commonly in elderly women with long-standing undiagnosed or undertreated hypothyroidism in whom an additional significant stress is experienced. Numerous precipitating factors have been identified (Box 70.4).

Box 70.4

Factors precipitating myxoedema coma

- Infection
- Cold environmental temperatures/hypothermia
- Burns
- Stroke
- Surgery
- Trauma
- Congestive heart failure
- Carbon dioxide retention
- Gastrointestinal haemorrhage
- Hypoglycaemia
- Medications
    - Amiodarone
    - Anaesthetic agents
    - Analgesics/narcotics
    - Beta-blockers
    - Diuretics
    - Lithium
    - Phenytoin
    - Rifampicin
    - Sedatives/tranquilisers

Clinical Presentation

Myxoedema coma can be defined when decreased mental status, hypothermia and clinical features of hypothyroidism are present (Box 70.5). When these features are present, diagnosis is straightforward; however, asymptomatic or atypical presentation (e.g. decreased mobility) may occur. [39] The presence of hypotension and bradycardia at presentation, a need for mechanical ventilation, hypothermia unresponsive to treatment, sepsis, intake of sedative drugs, lower Glasgow Coma Scale (GCS), high APACHE II score and high Sequential Organ Failure Assessment (SOFA) score have been associated with an increased predicted mortality. [40] Patients may also present with clinical manifestations of the acute event that precipitated the myxoedema coma (e.g. sepsis and myocardial infarction) though it is important to note that patients with infection may have a blunted febrile response due to loss of thyroid hormone-mediated thermogenesis.

Box 70.5

Clinical features of myxoedema coma

- Neuromuscular
    - Abnormal conscious level
    - Psychiatric alterations
    - Weakness
    - Slow relaxing reflexes
    - Fatigue
- Hypothermia
- Cardiovascular
    - Diastolic hypertension
    - Bradycardia
    - Low cardiac output
    - Pericardial effusions
    - Electrocardiography alterations
- Respiratory
    - Diminished central response to hypoxia and hypercapnia
    - Respiratory alkalosis

  - Respiratory muscle weakness
  - Increased sensitivity to sedative drugs
  - Pleural effusions
  - Sleep apnoea
- Airway
  - Deep voice, goitre, vocal cord oedema and macroglossia
- Gastrointestinal
  - Gastric atony, distension, paralytic ileus, faecal impaction and megacolon (late)
  - Weight gain
  - Malabsorption
  - Ascites (rare)
- Bladder distension, urinary retention
- Cold intolerance
- Coarse hair
- Dry, pale, cool skin
- Laboratory abnormalities
  - Hyponatraemia
  - Hypoglycaemia

Neuromuscular

Alteration of conscious or mental state is present in all patients. This can range from depressive symptomatology ranging from personality change to coma to a more activated presentation with overt psychosis, so-called ‘myxoedema madness’. About 25% of patients experience seizures prior to the onset of coma. Electroencephalogram usually reveals non-specific changes. Weakness is common and skeletal muscle dysfunction may develop secondary to increased membrane permeability. The latter can lead to a rise in creatine phosphokinase. Hyponatraemia is present in up to 50% of patients and may contribute to alterations in conscious level. Lumbar puncture often reveals elevated protein levels and a high opening pressure.

Hypothermia

Hypothermia represents the decrease in thermogenesis that accompanies reduced metabolism and is exacerbated by low ambient temperatures. Mortality is proportional to the degree of hypothermia. A low-reading thermometer should be used during the assessment.

Cardiovascular Features

Diastolic hypertension is due to increased systemic vascular resistance and blood volume reduction [41] ; however, myxoedema is associated with bradycardia and impaired myocardial contractility, with reduced cardiac output and hypotension a common feature. While pericardial effusions may occur, tamponade is uncommon. Creatine phosphokinase may be elevated, though this more commonly originates from skeletal rather than cardiac muscle. Acute coronary syndrome must nevertheless be excluded as a precipitant of the crisis. Electrocardiography (ECG) changes include bradycardia, decreased voltage, non-specific ST and T changes, varying types of block and prolonged QT interval. All of the cardiovascular abnormalities are reversible with thyroid hormone treatment. [42]

Respiratory Features

Hypothyroidism causes numerous respiratory alterations (see Box 70.5). There is a propensity for respiratory alkalosis, particularly during artificial ventilation. This is due to low metabolic rate which may be compounded by iatrogenic hyperventilation. [43] Diaphragmatic weakness may occur due to abnormalities of the phrenic nerve; as a result, exercise tolerance may be significantly reduced. These abnormalities improve with thyroid hormone replacement, though full recovery can take several months.

Laboratory Findings

TFTs will reveal low T_4 and T_3 ; TSH is raised in primary and low in secondary and tertiary hypothyroidism.

Hyponatraemia is common and usually develops due to free water retention resulting from excess vasopressin secretion or impaired renal function. [44] It may be severe and can contribute to diminished mental function. Although total body water is increased, intravascular volume is usually decreased.

Hypoglycaemia may result from hypothyroidism alone, or as a result of concurrent adrenal insufficiency (Schmidt's syndrome). The mechanism is probably reduced gluconeogenesis, but infection and starvation may contribute.

Azotaemia and hypophosphataemia are common; renal function may be severely abnormal due to low cardiac output and vasoconstriction. Mild leucopenia and normocytic anaemia are frequently present, though macrocytic and pernicious anaemia due to autoimmune dysfunction may occur.

Arterial blood gases often reveal respiratory acidosis, hypoxia and hypercapnia.

Management

The mainstay of therapy consists of thyroid hormone replacement, steroid replacement and supportive measures in an intensive care setting. Once clinical diagnosis has been made or is suspected, blood should be collected for thyroid function and plasma cortisol tests. This should be followed by thyroid hormone treatment, which should not be delayed while awaiting laboratory results. Consideration should be given to identifying and treating precipitating factors and complications of the crisis.

Thyroid Hormone Therapy

All patients with suspected myxoedema coma should receive presumptive treatment with thyroid hormone. The optimum speed, type, route and dose of thyroid hormone replacement in myxoedema coma are unknown due to the rarity of the condition and paucity of trials. The severity of clinical presentation does not correlate with the doses of replacement hormone that are required. Rapid replacement can result in life-threatening myocardial ischaemia or arrhythmias; delayed therapy exposes patients to the prolonged risk of complications from the crisis. Both scenarios are associated with increased mortality.

Some experts favour administration of T_3, as it is biologically more active, has more rapid onset of action and bypasses the impaired deiodination of T_4 to T_3 which occurs in hypothyroidism and non-thyroidal illness. High serum T_3 concentration has, however, been associated with increased mortality [45] and T_3 is expensive and may be difficult to obtain. T_3 may be administered orally or intravenously and has been combined with T_4 therapy. [46,47] In one study of 23 successive patients suffering from myxoedema coma, those who received oral L-thyroxine had no difference in outcome from those receiving intravenous (IV) thyroxine. [40]

Most authorities recommend the use of T_4 alone, [45,47,48] as the delayed conversion to T_3 allows more gradual replacement of the deficient hormone. Bioavailability of orally administered T_4 is unpredictable given the high incidence of gastrointestinal dysfunction; therefore, intravenous administration is more frequently used. A loading dose of intravenous levothyroxine 100–500 µg is recommended, [47] as this saturates the binding proteins. This should be followed by 50–100 µg daily until conversion to the bioequivalent oral formulation is possible. The doses must be adjusted to allow for patient age, weight and cardiovascular risk factors; the lower doses should be administered to patients who are elderly, frail or have co-morbidities (particularly cardiovascular disease). Free T4 and T3 levels should be measured at a minimum of every 2 days to confirm response to therapy.

Corticosteroids

Corticosteroids are an important part of treatment, as relative or absolute hypoadrenalism may occur concurrently with hypothyroid disease. A random serum cortisol level should be collected prior to commencing hydrocortisone therapy at 100 mg 8-hourly. If an ACTH stimulation test is warranted, dexamethasone 4 mg 6-hourly should be commenced with conversion to hydrocortisone or cessation of treatment once the results are known. If random serum cortisol levels return to normal levels, steroid treatment can be discontinued.

Supportive Therapy

Hypothermia should be treated by passive re-warming where possible but active measures may be required. Appropriate cardiovascular, temperature gradient, electrolyte and acid-base monitoring should be provided during the re-warming phase to prevent haemodynamic and metabolic compromise.

Numerous alterations in respiratory physiology occur, including hypoventilation and altered response to arterial oxygen and carbon dioxide tensions. In addition, anatomical changes to the airway, delayed gastric emptying and increased sensitivity to sedative drugs may be present. These changes should be considered when mechanical ventilation is required, particularly during intubation and the weaning process. [43]

Patients usually present with intravascular fluid depletion despite peripheral oedema. Cardiac output monitoring may help guide fluid resuscitation and therapy. Echocardiography is useful in identifying cardiac dysfunction, pericardial effusions and assisting in the assessment of intravascular volume status. Cardiac monitoring should be used to alert to the presence of arrhythmias. Inotropes and vasopressors should be avoided where possible due to their potential to precipitate cardiac arrhythmias. Where inotropes are required, increased dosage may be necessary as reduction in β-adrenoceptors is common; α-adrenoceptor function is usually preserved.

Hyponatraemia is reversible with thyroid hormone treatment, but severe abnormalities contributing to neurological dysfunction may require more expeditious correction. Free water intake should be restricted and hypertonic saline solutions may be required. Hypotonic fluid therapy should be avoided. If glucose therapy is required, hypertonic solutions (20%–50%) should be infused via a central venous catheter.

Precipitating factors must be considered. As with all critically ill patients, microbial cultures should be collected and antibiotic therapy commenced unless cultures are negative. Prophylaxis against venous thromboembolism and peptic ulceration should be considered. Enteral feeding should be attempted but may be unsuccessful if gastrointestinal dysfunction and stasis are present.

Non-Thyroidal Illness

Non-thyroidal illness describes the phenomenon of starved or systemically unwell patients with abnormal serum TFTs but with no apparent thyroidal illness. Low T_3, T_4 and TSH are commonly found, with the degree of abnormality correlating with the severity of illness. Variants of these hormone levels are well described. Low serum T_3 is a frequent finding and occurs due to down-regulation of the monodeiodinase enzyme that converts T_4 to T_3, while rT_3 may increase due to increased activity of the T_4-to-rT_3 monodeiodinase.[49]

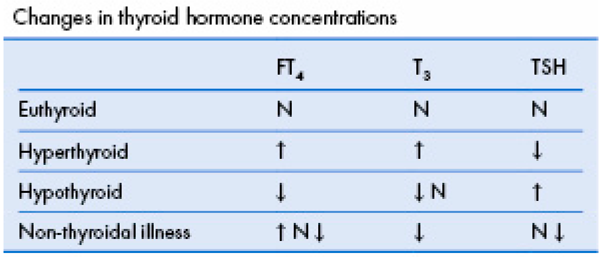
Serum T_4 is also commonly low in the critically ill. This is due to a decrease in the concentration of thyroid hormone-binding proteins and the presence of inhibitors that reduce T_4 binding to these proteins. There is also a suggestion that T_4 entry into cells may be impaired.[50] Free T_4 levels should be normal in less severe illness; however, in severe illness, the level may be low due to inadequate correction during the fT_4 assay.[51]

Low serum TSH levels were previously thought to be associated with the euthyroid state; however, more recent work suggests that acquired transient central hypothyroidism is present in these patients.[52] Cytokines such as tumour necrosis factor-α are known to inhibit TSH secretion. Such phenomena are probably evolutionary adaptations to conserve protein and energy during severe illness. Elevated TSH may also occur in non-thyroidal illness, but few of these patients prove to have hypothyroidism following recovery from their acute illness.

Changes in TFT are well described during starvation, sepsis, bone marrow transplantation, surgery, myocardial infarction, coronary artery bypass surgery and probably any critical illness. However, the replacement of thyroid hormone in these patients is of no benefit and may be harmful[53]; hence, thyroid function should not be assessed in critically ill patients unless there is a strong clinical indication to do so. A number of specific non-thyroidal illnesses are associated with abnormal TFTs. These include some psychiatric illnesses, hepatic disease, nephritic syndrome, acromegaly, acute intermittent porphyria and Cushing’s syndrome. Where assays are performed, TSH should not be interpreted in isolation as low values will not discriminate between true thyroid versus non-thyroidal disease. If low T_4 is also present, non-thyroidal illness is likely. If T_4 is elevated, then hyperthyroidism is the likely diagnosis, though elevated T_4 has been documented in non-thyroidal illness.

Given the alterations in these hormones and difficulties with their assay during critical illness, thyroid hormone replacement should not be undertaken on the strength of TFT results alone; additional laboratory and clinical indications must also be present (Table 70.2).

Table 70.2



Changes in thyroid hormone concentrations

	FT_4	T_3	TSH
Euthyroid	N	N	N
Hyperthyroid	↑	↑	↓
Hypothyroid	↓	↓ N	↑
Non-thyroidal illness	↑ N ↓	↓	N ↓

↑, Increased; ↓, decreased; *FT* $_4$, free tetraiodothyronine; *N* , normal; *T* $_3$, triiodothyronine; *TSH* , thyroid-stimulating hormone.

Adrenocortical insufficiency in critical illness

Jeremy Cohen and Bala Venkatesh

Physiology

The adrenal glands are functionally divided into medulla and cortex; the latter is responsible for the secretion of three major classes of hormones; glucocorticoids, mineralocorticoids and sex hormones. The major pathogenic effects of disease result from cortisol and aldosterone deficiency.

Secretion is under the control of the hypothalamic-pituitary axis (Fig. 71.1). There are a variety of stimuli to secretion, including stress, tissue damage, cytokine release, hypotension and hypoglycaemia. These factors act upon the hypothalamus to favour the release of corticotrophin-releasing hormone (CRH) and vasopressin. CRH is synthesised in the hypothalamus and carried to the anterior pituitary in portal blood, where it stimulates the secretion of adrenocorticotrophic hormone (ACTH), which in turn stimulates the release of cortisol, mineralocorticoids (principally aldosterone) and androgens from the adrenal cortex. During periods of stress, trauma or infection, there is an increase in CRH and ACTH secretion and a reduction in the negative feedback effect, resulting in increased cortisol levels, in amounts roughly proportional to the severity of the illness. The schematic representation illustrates neural and hormonal control of glucose regulation through interconnected organs and processes. The top section includes the brain, showing input to the hypothalamus and onward to the pancreas. Arrows from the pancreas lead to the liver and a glucose channel. A glucose transporter connects to an insulin signal pathway. The image also depicts beta cell release of insulin and its effect on glucose transport. Labelled arrows indicate steps including neural stimulation, glucose sensing, insulin secretion, and cellular glucose delivery. A dashed line marks the blood and tissue boundary. Additional components include the gastrointestinal tract and glucose sensor proteins. Directional arrows represent inhibitory and stimulatory effects.

FIG. 71.1 The hypothalamo-pituitary-adrenal axis.

Cortisol is transported in the blood to the tissues in three fractions; approximately 80% is closely bound to corticosteroid-binding globulin (CBG), 10%–15% is loosely bound to albumin and 5%–8% as a free fraction. At normal levels of total plasma cortisol (e.g. 375 nmol/L or 13.5 µg/dL) less than 5% exists as free cortisol in the plasma; however, it is this free fraction that is biologically active. Currently, available routine assays measure only total cortisol levels; bound and free.

The actions of cortisol are mediated by the glucocorticoid receptor, a member of the nuclear hormone receptor superfamily. Free cortisol passes through the cell membrane and binds to the glucocorticoid receptor, activating it. The activated receptor migrates to the nucleus and binds to specific recognition sequences within target genes, but also interacts with numerous transcription factors and cytosolic proteins. Intracellular concentrations of cortisol can be altered by the actions of the 11-beta-hydroxysteroid enzyme system which regulates the interconversion of cortisol and cortisone (Fig. 71.1).

Cortisol has a half-life of 70–120 min. It is eliminated primarily by hepatic metabolism and glomerular filtration. The excretion of free cortisol through the kidney represents 1% of the total secretion rate. It appears that cortisol clearance from the plasma is reduced in critical illness, leading to an increase in systemic cortisol availability. [4]

The metabolic effects of cortisol are complex and varied. In the liver, cortisol stimulates glycogen deposition by increasing glycogen synthase and inhibiting the glycogen-mobilising enzyme glycogen phosphorylase. [5] Hepatic gluconeogenesis is stimulated, leading to increased blood glucose levels. Concurrently, glucose uptake by peripheral tissues is inhibited. [6] Free fatty acid release into the circulation is increased and triglyceride levels rise.

In the circulatory system, cortisol increases blood pressure both by direct actions upon smooth muscle and via renal mechanisms. The actions of pressor agents such as catecholamines are potentiated; while nitric oxide-mediated vasodilation is reduced. [7, 8] Renal effects include both an increase in glomerular filtration rate, sodium transport in the proximal tubule and sodium retention and potassium loss in the distal tubule. [9]

The primary effects of cortisol on the immune system are anti-inflammatory and immunosuppressive. Lymphocyte cell counts decrease, while neutrophil counts rise. [9] Accumulation of immunologically active cells at inflammatory sites is decreased. The production of cytokines is inhibited, an effect that is mediated via NF-kB. This occurs both by induction of NF-kB inhibitor or by direct binding of cortisol to NF-kB, thus preventing its translocation to the nucleus. While the well-defined effects of cortisol on the immune system are primarily inhibitory, it is also suggested that normal host defence function requires some cortisol secretion. Cortisol has been described to have a positive effect on immunoglobulin synthesis, potentiation of the acute phase response, wound healing, and opsonisation. [10]

Classification of Adrenal Insufficiency

Adrenal insufficiency (AI) may be considered to be primary, secondary or tertiary. Primary AI, or Addison’s disease, results from hypofunction of the adrenal cortex. Secondary AI occurs when there is suppression or absence of ACTH secretion from the anterior pituitary. Tertiary AI describes a situation of impaired secretion of CRH or vasopressin from the hypothalamus. Secondary and tertiary forms are often collectively known as central AI. In the setting of critical illness, a further classification has been proposed; that of critical illness-related corticosteroid insufficiency (CIRCI). CIRCI represents a situation of disturbed glucocorticoid metabolism which may result in an inadequate response to the physiological stress of severe illness.

Primary Adrenal Insufficiency

Primary AI is a rare disorder. In the Western world, its estimated prevalence is 120 per million. [11] In adulthood, the commonest cause is autoimmune, but in the intensive care setting, consideration should be given to other causes of adrenal gland destruction (Table 71.1). These include infection, haemorrhage and infiltration. Tuberculosis is the commonest infective cause worldwide, but rarer infections such as histoplasmosis, coccidiomycosis and CMV (especially in patients with HIV) have also been implicated. Haemorrhage into the glands is associated with septicaemia, particularly meningococcal (Waterhouse-Fredrickson syndrome). Asplenia and the antiphospholipid syndrome may also be associated with adrenal haemorrhage. Adrenal gland destruction may also be secondary to infiltration by tumour, or amyloid.

Table 71.1

Drugs may impair adrenal function either by inhibiting cortisol synthesis (etomidate, ketoconazole) or by inducing hepatic cortisol metabolism (rifampicin, phenytoin). High levels of circulating cytokines are also reported to have a suppressive effect on ACTH release. [12]

Presentation (Table 71.2)

The disease is often unrecognised in its early stages as the presenting features are ill-defined. Symptoms include tiredness and fatigue, vomiting, weight loss, anorexia and postural hypotension. Hyperpigmentation is seen in non-exposed areas (such as palmar skin creases) and is due to the hypersecretion of melatonin, a breakdown product from the ACTH precursor pro-opiomelanocortin (POMC).

Table 71.2

Presentation to an intensive care physician is likely to be in the form of adrenal crisis. This may be precipitated by concurrent illness or surgery, or by failure to take replacement medication. Classically, adrenal crisis will present as refractory shock with a poor response to inotropic or pressor agents. Abdominal or flank pain is often present and may lead to an erroneous diagnosis of an acute surgical abdomen.

Treatment should consist of immediate supportive measures, fluid resuscitation and high-dose intravenous glucocorticoid therapy. A standard dose would be 100 mg of hydrocortisone 6 hourly, or as an infusion. At these doses, separate mineralocorticoid replacement is not required. [13]

Adrenal crisis should be suspected in cases of undifferentiated shock not responding to standard management. Suggestive features would include a history of symptomatology consistent with the diagnosis, hyperpigmentation on examination and demonstration of hyponatraemia, hyperkalaemia and peripheral blood eosinophilia. A random plasma total cortisol taken during a crisis will be low (below 80 nmol/L) and in the acute phase, ACTH stimulation testing is not required.

Central Adrenal Insufficiency

The commonest cause of ACTH deficiency is sudden cessation of exogenous glucocorticoid treatment. Patients who have been taking more than 30 mg/day of hydrocortisone or equivalent for more than 3 weeks are at risk of adrenal suppression. [9] Other causes include pituitary surgery, pituitary infarction (Sheehan's syndrome), pituitary tumour and hypothalamic damage.

Presentation is similar to that of primary AI. The major distinguishing characteristics are a lack of hyperpigmentation, and the absence of mineralocorticoid deficiency; hence hyperkalaemia is not a feature of secondary AI, although hyponatraemia may still be present due to increased vasopressin levels.

Investigation of Adrenal Insufficiency

In a stable patient, suspected AI is routinely investigated by an ACTH stimulation test. The test is performed by administering 250 µg of a synthetic ACTH molecule comprising first 24 amino acids; tetracosactrin (Synacthen). Plasma total cortisol is measured at 0 and 30 minutes after administration, and a normal response is defined as a peak cortisol measurement over 525 nmol/L. [14] However, it should be noted that current immunoassays exhibit a significant degree of variability, and thus local laboratory reference ranges should be used. [15] The test cannot be performed if the patient is currently being prescribed hydrocortisone as this will cross-react with the assays; an alternative replacement therapy such as dexamethasone should be used in these cases.

Central AI may be differentiated from primary by a prolonged ACTH test. This is performed by the use of a depot preparation or an intravenous infusion of tetracosactrin for 24–48 hours. Patients with central hypoadrenalism show a greater plasma cortisol response at 24 hours than at 4 hours; alternatively, measurement of a baseline ACTH level may be used. In patients with primary AI, this will be elevated.

Other biochemical tests that may be used in investigation of AI include the insulin hypoglycaemia test; the overnight metyrapone test; and the CRH stimulation test. These investigations are not normally necessary in uncomplicated cases. In addition, the use of the low-dose ACTH stimulation test has been advocated in which only 1 µg of tetracosactrin is used. This approach has not yet gained widespread acceptance.

Critical Illness-Related Corticosteroid Insufficiency (CIRCI)

Substantial alterations in glucocorticoid metabolism occur in response to critical illness.

Annane et al. prospectively studied 189 patients with septic shock and detailed a three-level classification system based on the basal cortisol level and response to ACTH. [16] Mortality was found to be highest in those patients with a basal cortisol level above 34 µg/dL (938 nmol/L) and response to ACTH of less than 9 µg/dL (248 nmol/L). Patients with a basal cortisol above 34 µg/dL but a cortisol response greater than 9 µg/dL, did better, while the best prognosis was seen in the group with a lower basal cortisol level and high response to ACTH. A similar pattern has been observed in numerous other studies of patients with both septic and non-septic critical illness. The significance of this observation, however, is not clear. It has been suggested to either represent a partially suppressed adrenal axis, implying a role for cortisol replacement therapy, or alternatively as indicating an ‘overstressed’ axis, in which case steroid treatment would be inappropriate. Treatment of septic patients fulfilling CIRCI criteria with hydrocortisone has been shown to improve outcomes only in one study,[17] but these results have not been reproducible in larger trials.[18] Alternative diagnostic criteria, relying on baseline plasma cortisol levels without ACTH stimulation have been proposed,[19] but the lack of a consistently observed relationship between cortisol levels and mortality means that the optimal diagnostic criteria for CIRCI remain controversial (see Table 71.3). Possible explanations for the difficulties in assessing adrenal function in this patient group include spontaneous fluctuations in the measured cortisol values[20]; increased variability of assays[15]; and changes in CBG levels affecting free cortisol values.[21],[22] Measurement of the free cortisol fraction, representing the bioavailable active hormone, has been the focus of recent research interest, with some evidence suggesting it may give a more accurate representation of adrenal function.[21],[22] However, the superiority of free cortisol estimations is by no means clear[23–25] and the limited availability of the assay means the test is not in general clinical use. A biochemical sub-study of a large randomised trial in septic shock demonstrated that cortisol (either total or free) levels at baseline were of no value in predicting if patients would respond to corticosteroid treatment.[26]

Table 71.3

HDSST , High-dose short Synacthen test; *SST* , short Synacthen test

An alternative hypothesis put forward to explain the constellation of adrenocortical changes in critical illness is a sick euadrenal syndrome analogous to the sick euthyroid state,[27] in which changes in the free cortisol fraction, intracellular cortisol:cortisone interconversion, glucocorticoid receptor density and gene transcription may all act to effect adrenal function at a tissue level. Evidence indicates that tissue sensitivity to the action of glucocorticoids in patients with septic shock is highly variable, and cannot be accurately assessed using plasma cortisol concentrations. [28] Other reports suggest that CIRCI may be secondary to central HPA axis suppression, particularly in prolonged critical illness, but precise diagnostic criteria for such a syndrome are lacking. [4]

In summary, the concept of CIRCI remains controversial, and there appears to be little role for the routine measurement of cortisol concentrations or corticotrophin testing in critically ill patients in whom there is no suspicion of primary or central AI.

Steroid Therapy in Critical Illness

Steroids have an established role in the management of a number of critical illnesses as outlined in Table 71.4 . However, their use in other conditions has not been without controversy:

Table 71.4

Spinal injury

High-dose methylprednisolone has been advocated in the management of patients with spinal cord injury following the publication of the NASCIS II and III trials. The major criticism of these studies is the lack of a demonstrable improvement in the primary outcome measures. For a more detailed review of the use of steroids in spinal cord injury, the reader is referred to Chapter 81 .

Head Injury

The role of steroids in the management of cerebral oedema secondary to tumours is well documented and accepted. However, their role in the management of head injury has been the subject of intense debate. Several prospective studies have not been able to prove any benefit of steroids in head trauma. The CRASH trial with nearly 10,000 patients clearly demonstrated the lack of any benefit with steroids in head injury. [29]

However, a more recent study of multiple trauma suggested that patients fulfilling the criteria for CIRCI had a lower rate of development of ventilator-associated pneumonia when treated with hydrocortisone [30]; these findings were more marked in patients with head injury. A replication study, however, failed to confirm this finding. [31]

ARDS

The ARDS clinical trial network published the results of its multi-centre study where corticosteroids were administered to patients with ARDS persisting beyond 7 days. Although steroid use was associated with earlier ventilatory wean, improved arterial oxygenation and increased respiratory compliance, there was a higher rate of return to assisted ventilation and neuromuscular weakness. [32] No overall mortality difference was demonstrable between steroid and placebo groups. Commencement of steroids more than 2 weeks after onset of ARDS led to almost a 4-fold increase in mortality as compared to the placebo group. Consequently, steroids cannot be routinely recommended for persistent ARDS and may be harmful in late-stage ARDS. Although one randomised controlled trial (RCT) demonstrated some benefit in early ARDS, trial design issues preclude widespread application of these results. [33] A recent multi-centre trial of early dexamethasone versus standard care in mechanically ventilated patients with ARDS demonstrated reduced duration of mechanical ventilation and overall mortality in patients with established moderate-to-severe ARDS assigned to dexamethasone. [34]

Corticosteroids were not found to be of benefit in ARDS associated with severe H1N1 pneumonia [35] but remain the treatment of choice in patients with COVID-19-associated ARDS requiring high levels of respiratory support. Dexamethasone at doses ranging from 6 to 12 mg was found to be associated with lower mortality and improved outcomes. [36], [37]

Septic Shock

Interest in the role of the adrenal cortex in the recovery from infection dates back nearly 100 years. Evidence from RCTs in the late 1980s demonstrated that high-dose methylprednisolone (30 mg/kg), although effective in reversing shock, did not reduce mortality in sepsis and that treatment with high-dose corticosteroids was in fact associated with increased mortality from superinfection.[38]

Clinical trials of using lower doses of corticosteroids in septic shock, typically hydrocortisone in a dose of 200 mg per 24 hours, demonstrated a more rapid reversal of shock with corticosteroid use. Two RCTs in 2002 and 2008 evaluating the efficacy of low-dose steroids in reducing mortality in patients with septic shock produced divergent results.[17,39] A subsequent trial comparing vasopressin and noradrenaline either with or without hydrocortisone[40] (VANISH) found no beneficial effect of the hydrocortisone, contradicting a subgroup finding from a previous study.[41] The HYPRESS study[42] found no effect of hydrocortisone on the prevention of the development of shock in unshocked patients with severe sepsis. In 2018, two large parallel-group RCTs of corticosteroids in septic shock were reported which have added substantially to the evidence base. The ADRENAL trial (n=3800) evaluated the role of 200 mg of hydrocortisone administered as an intravenous infusion in etomidate naïve mechanically ventilated patients with septic shock. While there was no difference in the 90-day mortality between the treatment groups, some secondary outcomes were better in the hydrocortisone group – faster reversal of shock, earlier time to liberation from mechanical ventilation, earlier time to ICU discharge and a lower incidence of blood transfusion.[43]

The APROCCHSS study (n=1241) evaluated the effect of hydrocortisone (200 mg) combined with fludrocortisone (50 mcg) versus placebo on survival from septic shock. The APROCCHSS study demonstrated a survival benefit in the active treatment arm (43% vs. 49.1%).[18] As in the ADRENAL trial, some secondary outcomes were also better in the steroid group. The precise role of fludrocortisone in the presence of hydrocortisone remains unclear. A robust randomised trial comparing hydrocortisone alone with hydrocortisone plus fludrocortisone would be needed to confirm any beneficial effect of fludrocortisone. In a recent patient-level meta-analysis of 17 trials, hydrocortisone compared with placebo was not associated with reduced mortality for patients with septic shock.[44] The most recent iteration of the Surviving Sepsis Campaign Guidelines provides a weak recommendation for using hydrocortisone for adults with septic shock and an ongoing requirement for vasopressor therapy.[45]

Cardiac Arrest

Little data exists on the role of glucocorticoids in post-cardiac arrest patients with shock. Similarities between the post-arrest shock state and septic shock have led to some advocacy for the use of steroid therapy in this condition. A blinded RCT, however, found no effect of hydrocortisone as compared with placebo, on the rate of shock reversal or mortality in vasopressor-dependent patients following cardiac arrest.[46] A recent RCT investigating the combination of methylprednisolone and vasopressin versus placebo for patients with in-hospital cardiac arrest reported a higher return of spontaneous circulation in the intervention group but no differences in survival or long-term neurological outcomes.[47]

Pneumonia

Adjunctive treatment with glucocorticoids has been advocated in the management of pneumonia as a strategy to reduce the systemic effects of locally produced pulmonary cytokines. Glucocorticoid treatment is routinely recommended for critically ill patients with pneumonia secondary to *pneumocystis jirovecii* infection in patients suffering from human immunodeficiency virus (HIV).[48] As previously noted, dexamethasone is considered the standard of care for patients with COVID-19 pneumonitis who have a requirement for supplemental oxygen therapy.[37] The data for pneumonia from other aetiologies is less clear. A pilot study reported an improvement in oxygenation and mortality in patients with severe pneumonia treated with seven days of hydrocortisone.[49] A larger trial in community-acquired pneumonia reported a reduced length of stay in patients receiving a four-day course of dexamethasone; however, only 5% of these patients required ICU care.[50] Conversely, a trial of seven days of prednisolone treatment in patients with community-acquired pneumonia showed no evidence of efficacy in either cure rate or length of stay[51] and an observational study of 316 patients with ICU-acquired pneumonia suggested that systemic steroid treatment was associated with an increase in mortality. [52] More recent blinded randomised trials have observed a shorter time to clinical stability in hospitalised patients with pneumonia treated for seven days with prednisolone, [53] as well as a reduced incidence of treatment failure. [54] A 2015 systematic review and meta-analysis suggested systemic corticosteroid therapy in this group reduced mortality by 3% and the need for mechanical ventilation by 5%. [55] In a recent blinded multi-centre RCT of 800 patients with community-acquired pneumonia, evaluating hydrocortisone versus placebo, patients assigned to hydrocortisone had a lower risk of death by day 28 than those who received placebo. [56] While the overall body of evidence would support the use of corticosteroids in pneumonia, a large platform trial (REMAP-CAP) is in progress in many countries and the results would inform future guidelines.

Meningitis

RCTs have demonstrated the benefit of early steroid therapy in paediatric meningitis particularly with *H. influenzae* infections. There is also evidence of benefit in adult patients with meningitis particularly with pneumococcal infections. However, in cryptococcal meningitis associated with HIV infection, there is evidence of harm [57] (for further detail refer to Chapter 63).

Side Effects of Steroid Therapy

Steroid therapy is associated with numerous side effects. Those that would be of particular relevance to intensive care are given in Table 71.5 .

Preoperative assessment of the high-risk patient

James Francis Waiting, Mevan Gooneratne and Don Milliken

Introduction

In the setting of an increasingly complex surgical population, preoperative assessment services are more important to the provision of high-quality, safe perioperative care than ever before. Many such services have expanded beyond their traditional functions and now play a central role in risk assessment, patient optimisation and shared decision-making for surgery. They often serve as an important link between patients and their surgeons, anaesthetists, critical care physicians and other perioperative clinicians. By generating and synthesising important clinical data, and by exploring patient wishes and priorities, they can make a vital contribution to surgical decision-making and outcomes. Patients should be referred to preoperative assessment services as early as possible in the preoperative pathway, maximising the time available for patient optimisation and decision-making.

Risk Assessment for Surgery

More than 300 million patients undergo surgery each year worldwide, and most are at low risk of perioperative major complications and death.[1,2] One of the primary functions of any preassessment service is to identify the minority of patients who are at increased risk of adverse outcomes. A shared understanding of risk forms an important basis of shared surgical decision-making and allows clinicians to individualise care to mitigate risk and improve outcomes.[3] Individualised risk assessment for high-risk major surgery should be conducted by senior clinicians with access to the patient's comprehensive clinical data.

Important Risk Factors

A diverse range of factors influence a patient's risk of adverse perioperative outcomes. Those with the most robust support for their utility in risk prediction include the specific operation, urgency of surgery, age and the American Society of Anaesthesiologists' Physical Status Classification System (ASA-PS).[4], [5] Other factors also may have a bearing on risk including blood test results, functional status, malignancy status, sex, body mass index and specific comorbidities, including diabetes, heart failure and chronic respiratory disease.[6], [7]

Important Outcomes

Perioperative risk assessment has traditionally focused on the risk of short-term mortality. However, it is increasingly recognised that other postoperative outcomes, including complications, functional status, quality of life and survival over the longer term, are of central importance to patients.[8] Estimating the likelihood of these outcomes may help patients to make better decisions about their care. This is especially relevant to patients at increased risk of adverse long-term outcomes, including those who are frail, who have reduced preoperative functional status, or who have poor preoperative exercise tolerance.

Risk Prediction Models

Risk assessment for major surgery should always be guided by expert clinical judgement but there is evidence that the use of quantitative, objective risk models can improve clinical decision-making and outcomes.[9], [10] There are a number of risk models in current clinical practice and the selection of an appropriate tool should be based on both methodological and pragmatic considerations.

A good risk model for major surgery requires only routinely available clinical data inputs, is easy to use and produces clear, unambiguous estimates of risk. Confidence in a model’s predictions is increased by the existence of high-quality validation studies demonstrating good discrimination and calibration in a sample of cases that are similar to the target case in terms of patient and surgical characteristics, care setting and geographic location. It is unfortunately common in clinical practice for risk models to be applied to patients very different from those in which they were validated, and we would recommend against this practice.

The Surgical Outcomes Risk Tool (SORT) was developed in the United Kingdom for the prediction of 30-day postoperative mortality and in validation studies has demonstrated good performance in several countries and health systems.[4,11–14] It requires only five routinely available clinical variables and a website (www.sortsurgery.com) provides a simple user interface. The second and latest version of the model demonstrates improved performance by incorporating clinician judgement into the risk estimate.[15]

Risk models for the prediction of other outcomes, including complications, discharge disposition and long-term disability, are less frequently used in clinical practice. Most do not demonstrate performance that would make them suitable to inform individualised, patient-level risk assessment. The American College of Surgeons National Surgical Quality Improvement Project Universal Risk Calculator uses a family of models to predict 12 postoperative outcomes and demonstrates excellent discrimination and calibration on internal validation.[7] Through a dedicated website (https://riskcalculator.facs.org/RiskCalculator/) it provides a useful graphical interface which contextualises the risk information by comparing it against the ‘average’ patient, and generates a report intended to be used by the patient. However, as the model coefficients remain unpublished, independent validation is difficult and it remains largely unvalidated outside the United States.[16–18]

It is important to consider that the output of most surgical risk prediction models is limited to a point estimate of risk. Recent models developed to predict mortality in emergency laparotomy emphasise uncertainty by displaying a probability distribution as well as a point estimate.[19] Development of similar tools for preoperative assessment for elective patients may help clinicians and patients to better appreciate the uncertainty associated with predictions, with the potential to improve patient and clinician decision-making.

Functional Capacity

Preoperative assessment of functional capacity can improve prediction of postoperative outcomes, including complications and survival, and forms an essential component of preoperative cardiovascular assessment.[20,21] Perhaps the most common approach is to ask the patient to report their own exercise tolerance, but recent evidence has called this practice into question and more objective forms of assessment may better support robust risk prediction.[22]

The Duke Activity Status Index (DASI) is a structured, self-reported assessment of functional capacity comprising 12 items. Unlike other functional assessment tools relying on self-report, there is high-quality evidence supporting its use in the prediction of postoperative major adverse cardiac events and mortality.[23] It is quick to administer and eminently scalable, providing the basis for cost-effective functional capacity assessment.

Cardiopulmonary exercise testing (CPET) provides the gold standard assessment of aerobic exercise capacity.[24] Physiological variables derived from the test, including the maximal oxygen consumption, anaerobic threshold and ventilatory equivalents for carbon dioxide, have been shown to predict a range of outcomes after major surgery.[20] However the test requires expensive equipment, a dedicated testing space and personnel with specific CPET training to administer and interpret the test – typically an exercise physiologist or anaesthetist. CPET is therefore not cost-effective for all patients undergoing major surgery and should be reserved for patients at greatest risk based on planned surgery, relevant comorbidity and self-reported functional status.

The incremental shuttle walk test (ISWT) and six-minute walk test (6MWT) are field walking tests that do not require expensive equipment or extensive training and are widely used in preoperative assessment. While they may have a role in screening patients for functional limitations, the current evidence supporting their use in the prediction of postoperative outcomes is weak and we would not recommend their use in this capacity.[25]

There is an unmet need for a new form of preoperative functional assessment that is well-validated, objective and scalable. There is emerging evidence for the use of novel techniques, including peak power output and wearable technologies that may offer utility in this space.[26], [27]

Frailty

There is evidence that preoperative frailty is associated with important postoperative outcomes including complications and mortality.[28] There are a number of frailty assessment tools currently in use and we would recommend the Clinical Frailty Scale on the basis that it is easy and rapid to administer and there is evidence to support its relationship with postoperative outcomes.[29]

Risk Modification

Preoperative risk modification should be individualised to address patient-specific risk factors, delivered by a multidisciplinary group of professionals, and include optimisation of comorbid disease, physical exercise, nutritional optimisation, psychosocial interventions, smoking cessation and correction of anaemia. While unimodal interventions (e.g. preoperative exercise alone) may reduce risk, the greatest improvements in risk profile are likely to require a multimodal approach whereby each intervention contributes to an overall substantial improvement in outcomes through an ‘aggregation of marginal gains’ approach.[30]

Optimisation of Comorbid Disease

Comorbid disease is increasingly represented in the surgical population and in the United Kingdom, with around 23% of patients burdened by multimorbidity. Older age and multimorbidity tend to coexist and both contribute to the complexity of perioperative care; 50% of the population aged over 65 are multimorbid. Multimorbidity is also more prevalent in areas of social deprivation and health inequality. [31,32] The multimorbid patient accounts for a large share of perioperative morbidity and mortality. [2,33]

Patients with comorbid disease should undergo a process of assessment and optimisation prior to surgery to reduce the risk of complications. Patients may work to optimise their comorbidities with their usual clinician or with a perioperative physician. The patient and perioperative physician should work with the surgical team to define a time frame for optimisation, and they should establish clear preoperative treatment goals. Disease-specific guidelines may support the development of a perioperative management plan. [32]

Patients who are likely to be at increased risk based on the severity of comorbid disease, poor functional status, or nature of surgery may be reviewed formally at a high-risk multidisciplinary team meeting. Here the diverse expertise of surgeons, anaesthetists, critical care physicians, general physicians, physiotherapists, dietitians and others may be used to guide treatment decisions regarding the appropriateness of surgery and to develop a perioperative management plan to optimise outcomes. [34] There is limited evidence suggesting that these meetings may alter treatment plans for most patients they review and that they may prevent prolonged stays in hospital. [35]

There is increasing evidence that an approach based on comprehensive geriatric assessment (CGA) may be helpful in optimising older patients for surgery. This involves a multidisciplinary assessment which addresses the patients' holistic needs and includes assessment of age-related frailty and cognitive decline. Within the fragility hip fracture population, perioperative CGA has been shown to reduce mortality, morbidity, length of stay and cost of treatment. [36]

Physical Exercise

The Centre for Perioperative Care (CPOC) recommends that all patients are assessed for physical activity levels and advised to improve their fitness prior to surgery. Exercise advice should be individually tailored to the patient's baseline fitness level and include moderate to high-intensity aerobic activity. [32] It is suggested that as little as two to three weeks of regular aerobic exercise can improve fitness levels. [37]

Systematic reviews have shown that preoperative exercise is associated with improvement across a range of postoperative outcomes including functional recovery, complications, mortality and length of hospital stay. However studies to date are heterogeneous with regard to interventions and outcomes, and the certainty of evidence relating to improvements is low. [37-39] Adherence to prescribed preoperative exercise programmes is highly variable, and it may be that supervised sessions lead to better adherence.

Exercise may be especially beneficial in those undergoing neoadjuvant chemoradiotherapy (NACT). NACT reduces cardiovascular fitness, as shown by a reduction in both peak oxygen uptake (VO_2 peak) and anaerobic threshold. [40] It may be that an exercise intervention during the interval between NACT and surgery is particularly effective, and in patients with rectal cancer undergoing NACT, a six-week exercise programme has been shown to return fitness levels to pre-treatment baseline. [41]

Nutritional Optimisation

Perioperative malnutrition increases complication rates, length of stay and mortality. [42] A study in German hospitals found over a quarter of inpatients to be malnourished, with increasing age, comorbidity and malignancy being major risk factors. Almost half of patients undergoing major abdominal surgery were at risk of malnutrition. [43]

All patients should be screened for malnutrition using a validated screening tool such as the Malnutrition Universal Screening Tool (MUST). [44] In mildly malnourished patients 7–10 days of nutritional intervention should be provided, with a longer period for the severely malnourished. [45]

Oral nutritional supplements given pre- and postoperatively have been shown to reduce length of stay, complication rates and mortality.[46]

Psychosocial Interventions

Patients at risk of psychological distress experience higher rates of postoperative complications.[32] Those being considered for major surgery should be screened for psychological distress with a validated screening tool and those found to be at risk should be referred for psychological support.

Smoking Cessation

The preoperative assessment clinic offers an opportunity to discuss smoking cessation. Smoking increases postoperative mortality and other adverse outcomes, including pulmonary complications, infections and wound complications. Prolonged exposure impairs cardiovascular and respiratory function.[47] Ideally patients should be encouraged to stop smoking at least four weeks prior to surgery, with a longer interval leading to a greater reduction in complications. Previously it was thought that smoking cessation just prior to surgery may increase the risk of complications but current data demonstrate no increase in risk.[48]

Correction of Anaemia/Patient Blood Management

Perioperative anaemia is associated with morbidity and mortality.[49] International consensus guidelines suggest that preoperative haemoglobin greater than 130 g/L should be targeted. If patients are at risk of greater than 500 mL surgical blood loss, anaemia should be investigated and treated before elective surgery. Nutritional deficiencies, including deficiencies of vitamin B_{12} and folate, should be corrected.

Patients should be screened for iron deficiency which may be defined, in the absence of systemic inflammation, by a serum ferritin less than 30 µg/L. Where the C-reactive protein (CRP) is greater than 5 mg/L, a transferrin saturation less than 20% and serum ferritin less than 100 µg/L support a diagnosis of iron deficiency. Oral iron should be used as first-line replacement and intravenous iron should be considered where oral iron is not tolerated or where surgery is scheduled less than 6 weeks from initiation of treatment. [50]

The PREVENTT trial compared treatment with intravenous iron against a placebo in patients undergoing major abdominal surgery. The trial revealed no effect of iron on the co-primary outcomes of blood transfusion and death, nor any reduction in postoperative complications. [51] Perioperative intravenous iron replacement had been widely adopted into clinical practice prior to this study and remains part of the perioperative management of many patients. It has been suggested that perioperative intravenous iron may improve functional capacity and response to exercise programmes. [52] International guidelines have yet to be updated since the publication of PREVENTT and further research is required to assess the utility of iron treatment in improving patient-centred outcomes.

Communicating Risk

As already discussed, it is exceptionally difficult to accurately estimate individualised perioperative risk prior to surgery. Conveying risk to patients in a meaningful way that supports them to make decisions about their own healthcare provides a further challenge. It has long been assumed that the traditional outcomes that clinicians hold dear, such as 30-day morbidity and mortality, are also valued by the patient. The recent shift towards patient-reported outcomes highlights the need to identify the outcomes that are important to each patient prior to surgery to aid their decision-making. [53] Accurate risk estimation relies on a combination of clinical experience, scoring systems and measurement of physiological fitness. Unfortunately, even the best clinical risk estimation methods are associated with significant uncertainty which can reduce the quality of the shared decision-making process.

Even if it were possible to accurately estimate individualised perioperative risk, we rely upon the ability of the patient to understand risk information and use it to inform their decisions. Clinicians would regard a mortality risk of 4% as high risk for minor surgery, but to the non-clinically minded a 96% chance of surviving surgery may appear favourable. It is for this reason that while risk stratification tools such as SORT are useful aids for clinicians, reciting the results to patients does not necessarily confer the magnitude of risk in the absence of important contextual information. Furthermore, patient understanding can be confounded by poor literacy skills as well as socioeconomic status.[54] For instance, Cancer Research UK demonstrated that 46% of patients did not know whether a risk of 1 in 100, 1 in 10 or 1 in 1000 implied a greater chance of cancer occurrence.[55]

Poor health literacy, that is, low motivation and ability to access, understand and use information in a way which enables good health, is associated with excess mortality and morbidity.[56], [57] It is important to identify patients with poor health literacy and support them by using patient-centred communication and education techniques.[58]

Shared Decision-Making

Historically, there has been an emphasis on clinicians, as experts, taking the primary role in making healthcare decisions on behalf of the patient. Even when clinicians feel they have successfully engaged patients in their care, surveys often reveal that they have not, citing failures to address patient values, preferences and goals.[59] Failure to overcome language barriers, poor educational backgrounds, and challenges when communicating with the elderly have led to approximately 15% of patients having an inadequate understanding of their diagnosis and intended procedure.[60] This may lead to poor patient satisfaction and loss of trust between clinicians and patients and may impair the validity of consent.

As a result, we have seen a shift in the patient–doctor paradigm with a move away from paternalistic medicine and towards shared decision-making. The ambition should be for clinicians to share the best available evidence when faced with the task of making decisions, and for patients to be supported to consider options and achieve informed preferences.[61] Both patient autonomy and clinician expertise should be respected as all treatment options are considered.

The global Choosing Wisely campaign has introduced the acronym ‘BRAN’ which highlights the key considerations when making shared decisions with patients (see Table 72.1).[62]

Table 72.1

BRAN approach to structuring a shared decision-making process

B	Benefits	What are the benefits of having surgery?
R	Risks	What are the risks of having surgery?
A	Alternatives	What are the alternatives to having surgery?
N	Nothing	What happens if surgery is not undertaken?

By structuring the consultation based on these four themes, clinicians can facilitate an extensive, unbiased, and evidence-based discussion. Table 72.2 provides is an example of how the BRAN format can be used to structure a conversation around colorectal cancer surgery.

Table 72.2

BRAN approach to colorectal cancer surgery

BRAN	**Clinician–Patient Discussion Points**
Benefits	Clarify whether the goal of surgery is curative or to relieve symptoms
Risks	Morbidity, mortality and length of stay Reduction in quality of life and functional status Increased dependency
Alternatives	Chemotherapy and/or radiotherapy Comparison of life expectancy with or without surgery Less invasive surgical or procedural options (e.g. bowel stenting)
Nothing	Exclude comorbid diseases (e.g. heart failure and COPD) which may affect life expectancy and impact on decision-making Symptom management plan

Input from a multidisciplinary team may be required to fully inform patients with complex medical problems of their surgical and non-surgical treatment options. Where a patient presenting for surgery has known comorbidity or where it is identified during perioperative assessment, the evaluation of geriatricians and other specialist physicians is often important to fully assess the attendant risks and provide a basis for high-quality shared decision-making. [63] This is especially true where comorbid disease may limit life expectancy and, in effect, compete with the risk imposed by their surgical diagnosis.

Informed Consent

Shared decision-making facilitates a better-informed and more robust consent process, ensuring that the clinician has fulfilled their duty to make the patient aware of the risks of surgery, while also setting expectations for the perioperative period. [64]

Recent medicolegal case law in the United Kingdom has shifted the emphasis of surgical consent towards a meaningful discussion that elicits and addresses patient concerns and away from attempting to present patients with an exhaustive list of risks. [65] The consent discussion that forms part of a shared decision-making process should be individualised and should prioritise the patient's goals and wishes.

The success of this approach depends upon the patient having ample time to deliberate over their options, and the clinician devoting sufficient time to listen to and understand the values and desires of the patient. Sensitive and effective communication in this context requires that patients receive sufficient emotional support and may be improved through the use of visual aids such as videos and diagrams. [66] The Patients Association paper 'Speak up for change' explains how the sharing of information should be extended to family and carers when appropriate. [67]

Postoperative cardiac intensive care

Nick Fletcher and Carlos Corredor

This chapter will cover the postoperative management of the common cardiac surgery procedures, including coronary artery bypass surgery, which is one of the most frequently undertaken surgical procedures globally, and surgery for valvular heart disease including minimally invasive, aortic and that for hypertrophic cardiomyopathy. Because of the high prevalence of cardiac disease in the population, cardiac surgery has significant health and economic implications. Intensive care may account for up to 40% of the total hospital costs for these patients and much of the short-term morbidity and mortality is due to perioperative complications.

The 30-day mortality following cardiac surgery is low (approximately 3%). However, this ranges from less than 1% for elective coronary artery bypass grafting to more than 30% for more complex surgery in patients with significant myocardial dysfunction and significant co-morbidities. Intensive care management following cardiac surgery usually involves a short period of recovery before discharge to the ward. For a small percentage of patients, significant complications may require the complete spectrum of high-acuity intensive therapy, with a profound impact on the intensive care unit (ICU) capacity, hospital budgets and resources.

Organisation

Types of Unit

The co-location of large numbers of patients with similar problems in cardiac ICUs provides an ideal environment for the standardisation of care based on protocols and clinical pathways. One of the pitfalls of postoperative cardiac care is that this apparent similarity of the patients tends to obscure their particularity. Individual patient assessment must carefully address the multisystemic manifestations of cardiovascular and other degenerative diseases. In some institutions, cardiac patients may be located with other surgical and medical intensive care patients to centralise critical care resources; staffing in particular. There is no adequate supporting evidence as to whether cardiac surgical patients have better outcomes with any particular model; rather, it is likely that high-quality dedicated critical care, constructive relationships with surgeons and a multidisciplinary culture will positively impact on the results. There has been significant research into organisational factors in general ICU; however, there is less supporting information around issues such as the ‘open’ versus ‘closed’ ICU model, and surgeon-led care versus intensivist-led care in the cardiac arena.

Surgeon/Intensivist Relationship

Cardiac surgery involves a continuum of care from presentation to post-discharge management and rehabilitation. The intensive care specialist must be involved in this continuum as part of a perioperative heart team, rather than functioning in isolation from surgeons, anaesthetists, cardiologists and even family practitioners.

The postoperative stage and outcome are largely set by the preoperative and operative phases of management, and it is the fitness of the patient to undergo surgery that is the primary determinant. [1] A component of postoperative management is active participation in patient selection and preparation, as well as in the conduct of anaesthesia and surgery. Relevant aspects include suitability and preparation for surgery, advanced care planning and more technical issues, such as temperature management, invasive monitoring, haemodynamic management and transport. Movement from the operating theatre to the ICU and onto the ward presents a potential hazard and will appear seamless only if the patient journey has been well coordinated in advance.

Joint selection and morbidity and mortality meetings may allow a forum to discuss complex cases and facilitate improvement of the institutional processes. In particular, the human factors, which are essential to successful cardiac surgery, may be put under the microscope. Regular audit of discharge timeliness, readmission and hospital mortality allows benchmarking against other units, both internal and external, and ensures good practices are maintained and poor practice is eliminated.

Outcome Audit

In the United States and the United Kingdom, risk-adjusted cardiac surgical results are available in the public domain by institution. EuroSCORE II is the predominant preoperative cardiac surgical risk score, but this performs less well as an ICU score. The majority of ICU scoring systems were not designed with cardiac surgery patients in mind; hence, some cardiac ICU-specific scoring systems have been more recently introduced. Currently, these are specific to different health systems.[2,3]

Types of Procedure

Changing patterns of practice are resulting in the management of older patients with more co-morbid pathologies. Procedures are now being offered to patients previously considered unfit for surgery, and there is a continuing growth in the use of minimally invasive forms of surgery. At the same time, patient and family expectations of surgical outcomes are increasing; this will increasingly impact cardiac intensive care practice.

Enhanced Recovery after Cardiac Surgery

Recently, the philosophy of enhanced recovery has been applied to the perioperative care of cardiac surgery patients. This is essentially an evolution of the fast-track methodology with the inclusion of a patient pathway including preoperative preparation, optimisation and education, intraoperative measures to facilitate rapid postoperative weaning from the ventilator, prompt extubation and early mobilisation. Guidelines which were published in 2019, and are currently being updated, have been widely adopted. [4] Some of the components relevant to critical care include pain management strategies, early extubation targets (within 6 hours) and goal-directed fluid therapy that uses monitoring techniques to guide the administration of fluid therapy, vasopressors and inotropes in order to avoid hypotension and low cardiac output. These rely on taking the methodology of enhanced recovery and developing locally adapted protocols. Early extubation and goal-directed fluid therapy have been demonstrated to shorten hospital stay following cardiac surgery rather than critical care unit stay. [5]

Immediate POST-OPERATIVE Management Principles

Structured Handover

The first step in ICU management involves a simple transfer of ventilation, monitoring and drug administration from transport to ICU systems. This should be structured to minimise disruption and maximise communication. The priorities are:

- Confirm the surgical procedure and any complications
- Highlight relevant patient-specific factors including co-morbidities
- Confirm the integrity and position of the endotracheal tube
- Re-establish mechanical ventilation of both lungs
- Re-establish all patient monitoring
- Confirm venous, arterial and central venous access
- Heart rhythm and presence and mode of any pacing devices
- Document results of any intraoperative echocardiography regarding ventricular function
- Communicate intraoperative transfusion of blood or blood products together with the results of any point-of-care tests (POCT) or laboratory tests of haemostasis

- An early 12-lead electrocardiograph to exclude or identify acute ischaemia.

Management is conveniently dictated by standardised protocols, which should cover investigations, fluid and electrolyte management, vasoactive and other drug administration and weaning and withdrawal mechanical ventilation. Standardisation is probably more important than the particulars of the protocol, which might vary considerably between institutions.

Haemodynamic Monitoring

Continuous invasive blood pressure and central venous pressure monitoring are standard following cardiac surgery and should be monitored during transfer to the ICU. Patients may become unstable during transfer and rapid assessment is needed to ensure the correct calibration of transducers, continuity of all infusions, evidence of hypovolaemia and haemorrhage. Cardiac output measurement by pulse contour analysis, pulse power analysis and a variety of ultrasound techniques is becoming more commonplace. Cardiac output-guided fluid boluses allow individualised treatment, and fluid unresponsiveness can guide inotropic and vasopressor use. Of note, pulse analysis is invalid in the presence of intra-aortic counterpulsation. In complex surgical patients, and those in which minimally invasive strategies are inappropriate, more invasive methods of haemodynamic monitoring are required. The use of flotation pulmonary artery (PA) catheterisation has become somewhat controversial. It is now reasonably well established that PA catheterisation is safe but may not alter outcomes. [6] However, there is a growing body of evidence that PAC monitoring may have a mortality benefit in the setting of cardiogenic shock. [7]

- Surgery can be safely undertaken, at least in low-risk patients, without PA catheterisation
- Collateral evidence supports PA catheter use in more complicated cases

- It is essential that the known limitations and complications of PA catheters are considered in usage and interpretation. [8]

Transoesophageal echocardiography (TOE) is now almost routine in the operating theatre, at least for more complicated patients. The technique is less suitable for monitoring in the ICU but is helpful in the diagnosis and management of cardiovascular instability in postoperative patients. Continuous TOE monitoring has been described, but the application is not widely used. [9]

Transthoracic echocardiography is of limited use postoperatively due to the poor cardiac windows. The apical window may allow some assessment of biventricular function and volume status. Inferior vena caval assessment is problematic and should not be used in this context. [10]

Intravenous Fluids

Despite generous intraoperative fluid administration, effective hypovolaemia is common in the early postoperative period, especially as vasodilatation occurs during postoperative warming.

- The use of balanced isotonic fluid is essential
- No benefit for any specific resuscitation fluid has been established
- Larger volumes of crystalloid than colloid solutions are required
- An excessively positive fluid balance may increase the risk of perioperative complications.

Polyuria is frequently observed in the early postoperative period, possibly related to hypothermia, haemodilution and the after-effects of non-pulsatile cardiopulmonary bypass on stretch and baroreceptors. This usually settles within the first 6 hours but often necessitates considerable volume replacement in the meantime. Use of goal-directed fluid protocols, which involve optimising stroke volume, for the first few hours after ICU admission can reduce adverse events and reduce hospital length of stay. [11]

Electrolytes

Hypomagnesaemia and hypokalaemia are common in the early postoperative stage and are exacerbated by polyuria. It is generally agreed that potassium levels should be maintained in the high normal range (4.5–5.0 mmol/L) although this has recently been challenged. [12]

Late hyperkalaemia may occur, especially in patients with renal impairment or prior angiotensin-converting enzyme (ACE) inhibitor administration. Treatment of hyperkalaemia is rarely required in the absence of significant renal impairment, but discontinuation of potassium-containing fluid may be needed. Calcium homeostasis is generally not disrupted by cardiopulmonary bypass. However, massive transfusion frequently causes hypocalcaemia. Ionised calcium levels are now easily monitored by point-of-care blood gas analysers.

Shivering

Shivering is frequent following cardiac surgery. Mechanisms are complex and not entirely related to core temperature. Shivering causes a significant increase in metabolic rate and hence cardiac workload. This is especially important in patients with impaired cardiac function and limited reserve. Forced air warmers are the most effective treatment, but pharmacological agents may be considered; these include dexamethasone, clonidine, pethidine and high-dose morphine. Short-term neuromuscular blockade is occasionally required.

Haemodynamic Complications and Management

Hypertension

Significant postoperative hypertension is more common in patients with a history of hypertension and with cessation of beta blockade, but is reasonably common in the early postoperative period. Both absolute pressure and maximal rate of rise of left ventricular (LV) pressure (dp/dt) are important factors in vascular injury. Complications associated with hypertension include:

- bleeding
- heart failure
- vascular (especially aortic) injury
- myocardial ischaemia.

Vascular resistance declines over the first few hours so that therapy during this period is best undertaken with agents with a short duration of action. [13] Glyceryl trinitrate infusions are often useful during the first 24 hours, after which regular oral medication can be restarted. Simple measures, such as the provision of adequate analgesia and sedation, also should be considered.

The target blood pressure varies with the indication. Excessive reduction of blood pressure risks reducing myocardial oxygen supply more than demand. Under most circumstances, a mean arterial pressure between 60 and 80 mmHg is optimal.

Hypotension

Hypotension is very common and can be a result of vasodilatation and low cardiac output (Table 73.1). Whatever the cause, hypotension can cause myocardial ischaemia and consequent heart failure. Hypotension has also been linked to the development of postoperative acute kidney injury (AKI). [14]

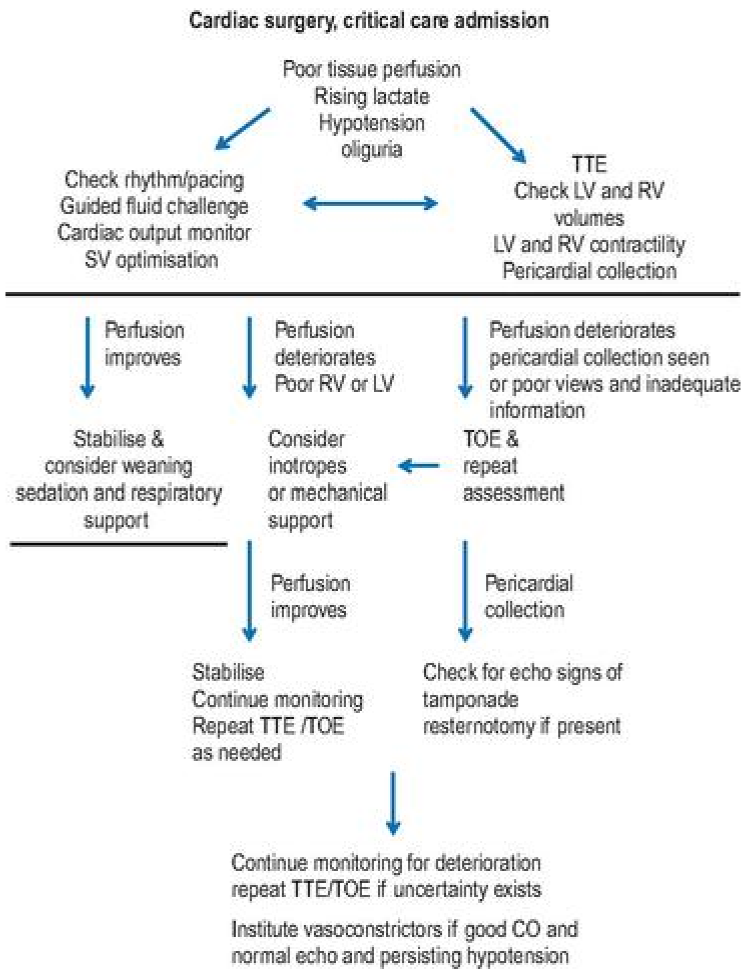
Table 73.1

In general, all patients should have some form of cardiac output monitoring to guide fluid, vasopressor and inotropic therapy. An initial straight leg raise manoeuvre enables fluid responsiveness to be evaluated safely. If not fluid responsive, vasoconstrictors may be useful in breaking the cycle of hypotension–ischaemia–hypotension, but must be used cautiously in patients with impaired ventricular function, and especially in patients with major vascular or aortic pathology, for whom a hypertensive overshoot may be catastrophic.

- Norepinephrine (noradrenaline) is a potent vasoconstrictor. It is commonly used to manage vasodilation, but it should not be used alone in the presence of a low cardiac output.
- Vasopressin has an increasing role in postoperative cardiac surgery; it reduces the level of norepinephrine (noradrenaline) required, and may thus spare the myocardium from excessive beta stimulation reducing the incidence of postoperative atrial fibrillation (AF) and may have a protective effect in terms of renal function.

Recognition of a low cardiac output state in the absence of invasive monitoring may be difficult. Many of the usual signs of low cardiac output are also consequences of anaesthesia and surgery. Tachycardia may be obscured by drugs, hypothermia and heart disease; hyperlactataemia can be an unreliable marker in this patient group. [13]

In the early postoperative period, a relatively low cardiac output may not warrant intervention, providing tissue oxygen delivery is adequate. Beta blockade is generally beneficial in the postoperative cardiac patient to prevent atrial fibrillation, but it should be used with caution in the presence of low cardiac output. Nevertheless, optimisation of cardiac function may confer some benefit [11] and intervention is required when surrogate markers of tissue oxygen delivery such as lactate indicate impending organ failure. On a specialised unit, an integrated algorithm can be used to assess and treat hypotension in sequence (Fig. 73.1). [10]



Cardiac surgery, critical care admission
Poor tissue perfusion
Rising lactate
Hypotension
oliguria
Check rhythm/pacing
Guided fluid challenge
Cardiac output monitor
SV optimisation
TTE
Check LV and RV volumes
LV and RV contractility
Pericardial collection
Perfusion improves
Perfusion deteriorates
Poor RV or LV
Perfusion deteriorates
pericardial collection seen
or poor views and inadequate information
Stabilise & consider weaning sedation and respiratory support
Consider inotropes or mechanical support
TOE & repeat assessment
Perfusion improves
Pericardial collection
Stabilise
Continue monitoring
Repeat TTE /TOE as needed
Check for echo signs of tamponade
resternotomy if present
Continue monitoring for deterioration
repeat TTE/TOE if uncertainty exists
Institute vasoconstrictors if good CO and normal echo and persisting hypotension

A clinical flowchart titled Cardiac surgery, critical care admission outlines the decision-making process for managing poor tissue perfusion following cardiac surgery, characterised by rising lactate, hypotension, and oliguria. The diagram presents two initial assessment branches, one involving checking rhythm and pacing, administering a guided fluid challenge, monitoring cardiac output, and optimising stroke volume and the other involving a transthoracic echocardiogram (T T E) evaluation to assess left and right ventricular volumes and contractility, along with identification of pericardial collection. If perfusion improves following the fluid-based approach, the patient is stabilised and weaning of sedation and respiratory support is considered. If perfusion deteriorates due to poor right or left ventricular function, inotropes or mechanical support are considered and once perfusion improves, stabilisation and continued monitoring are advised with repeat T T E or transesophageal echocardiogram (T O E) as needed. If perfusion worsens due to suspected pericardial collection or inadequate imaging, a T O E is performed for repeat assessment. If pericardial collection is confirmed, further evaluation is done to check for signs of tamponade, and resternotomy is considered if tamponade is present. All pathways converge at a final step recommending continued monitoring for clinical deterioration, repetition of T T E or T O E if uncertainty remains, and the use of vasoconstrictors if cardiac output is adequate but hypotension persists.

FIG. 73.1 Suggested simple practical algorithm for use of echocardiography in post-cardiac surgical patients. *LV* , Left ventricular; *RV* , right ventricular; *TOE,* tranoesophageal echocardiography; *TTE,* transthoracic echocardiography.

Mechanical ventilation is generally continued, reducing cardiac workload by removing the work of breathing. Positive intrathoracic pressure reduces LV afterload, which is beneficial to the dilated left ventricle. However, positive pressure ventilation may also be detrimental in the presence of diastolic ventricular dysfunction or hypovolaemia as the reduction in venous return may further reduce ventricular preload.

Tamponade

A high index of suspicion for tamponade is paramount in patients post-cardiac surgery. Any patient with a rising central venous pressure and low cardiac output should be assumed to have tamponade unless proven otherwise. Of note, hypotension may go unnoticed if vasopressors are being administered, thus haemodynamic monitoring is essential. Clinical assessment is difficult, and early echocardiography is required. Transthoracic images can miss posterior thrombus, but may be diagnostic and are more readily available. [15] Early discussion with the surgical team and TOE imaging will often be required. Management of impending tamponade is always a medical emergency as low cardiac output syndrome leads to deteriorating organ perfusion and the risk of cardiac arrest increases. Management is the release of the tamponade by drainage, usually involving re-sternotomy and investigation of the cause of bleeding. If time allows the patient should always return to the operating theatre.

Left Ventricular Dysfunction

Postoperative LV dysfunction is common and can be diagnosed by echocardiography or cardiac output monitoring. Inotropic agents are frequently required, alone or in combination with vasopressor agents. Pre-emptive use of inotropic drugs may be associated with harm, so they should not be used routinely without monitoring their effect. [16] Issues to consider include:

- Dobutamine is an essentially pure β_1-agonist. In the management of acute heart failure, it has been associated with an increase in mortality. [17]
- Epinephrine (adrenaline) is a potent inoconstrictor but its metabolic effects (especially lactic acidosis) and the relative tachycardia it causes make its use in cardiac surgical patients problematic. [18]
- Milrinone is a phosphodiesterase inhibitor with a long duration of action and potent vasodilating properties. These make milrinone relatively difficult to introduce and to wean. It has similar haemodynamic effects to dobutamine and is associated with increased atrial fibrillation (AF). Overall benefit is not established. [19] It may be a useful inotropic agent in patients with β-receptor down-regulation.

- Levosimendan is a calcium-sensitising agent. It offers little overall benefit in the treatment of heart failure, [20] but there is inconclusive evidence of benefit in the perioperative period. [21]
- Postoperative myocardial ischaemia predicts a more complicated postoperative course. Recognition is enhanced by automated ECG multilead ST segment analysis in conjunction with confirmatory 12 lead ECG, although diagnosis may be difficult in the presence of preoperative electrocardiographic abnormalities. [22]

Ischaemia may be due to graft failure, in which case remedial options include coronary angiography and/or reoperation. Angiography offers the potential for tailored reoperation or non-operative intervention. Management decisions may be influenced by surgical factors, such as the availability of further venous or arterial conduits for grafting and the state of the native coronary arteries. Thus close liaison among ICU personnel, cardiologists and surgeons is essential.

Delayed sternal closure has an established role in improving outcomes after cardiac surgery. [23] Cardiac output is increased and inotropic requirement is reduced. Subsequent sternal closure has an acceptably low complication rate. The sternum may be left open following an initial attempt at closure or reopened with later deterioration. Sternal retraction may be required.

Right Ventricular Dysfunction

Right ventricular (RV) failure following cardiac surgery is reasonably common. Aetiological factors include:

- direct RV ischaemia or infarction
- poor myocardial protection
- anteriorly placed RV
- pre-existing pulmonary hypertension.

Management involves:

- careful intravascular volume resuscitation

- maintenance of RV perfusion pressure with vasoconstrictors
- intra-aortic balloon counterpulsation (IABC) as required
- inotrope administration
- RV afterload reduction.

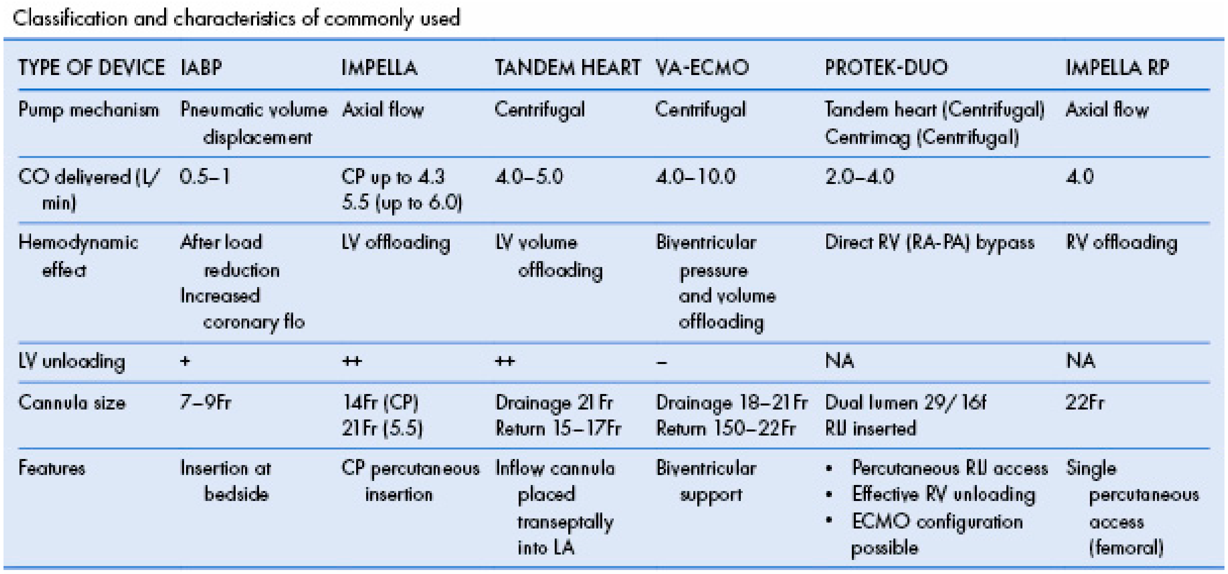
Useful RV afterload-reducing agents include nitric oxide, prostaglandins [24] and sildenafil. Conventional vasodilators tend to produce excessive systemic vasodilatation. Occasionally, RV balloon counterpulsation or an RV assist device may be required. Delayed sternal closure has an established role. [23] An understanding of the determinants of RV function and aetiology of failure is key to therapy. [25]

Mechanical Support

Cardiogenic shock post-cardiotomy occurs in approximately 1%–6% of cases, varying depending on the definitions and criteria used. In addition to pump failure other factors such as bleeding, coagulopathy and vasodilatation further compound management and outcome of post-cardiotomy shock. Mechanical circulatory support (MCS) is part of the therapeutic armamentarium available for the management of patients with postoperative cardiac dysfunction.

The selection of the appropriate MCS device depends on the patient's condition, surgical considerations and the expected duration of support required. The goal is to provide adequate circulatory support, maintain end-organ perfusion and allow for potential myocardial recovery or transition to more definitive therapies such as heart transplantation. [26] MCS devices can be classified depending on the duration of support as short-term/temporary or long-term/durable. They can also be classified according to their flow characteristics as centrifugal or axial flow pumps. [27] Currently, available short-term devices are outlined in Table 73.2 .

Table 73.2



Classification and characteristics of commonly used

TYPE OF DEVICE	IABP	IMPELLA	TANDEM HEART	VA-ECMO	PROTEK-DUO	IMPELLA RP
Pump mechanism	Pneumatic volume displacement	Axial flow	Centrifugal	Centrifugal	Tandem heart (Centrifugal) Centrimag (Centrifugal)	Axial flow
CO delivered (L/min)	0.5–1	CP up to 4.3 5.5 (up to 6.0)	4.0–5.0	4.0–10.0	2.0–4.0	4.0
Hemodynamic effect	After load reduction Increased coronary flo	LV offloading	LV volume offloading	Biventricular pressure and volume offloading	Direct RV (RA-PA) bypass	RV offloading
LV unloading	+	++	++	–	NA	NA
Cannula size	7–9Fr	14Fr (CP) 21Fr (5.5)	Drainage 21 Fr Return 15–17Fr	Drainage 18–21Fr Return 150–22Fr	Dual lumen 29/ 16f RIJ inserted	22Fr
Features	Insertion at bedside	CP percutaneous insertion	Inflow cannula placed transeptally into LA	Biventricular support	• Percutaneous RIJ access • Effective RV unloading • ECMO configuration possible	Single percutaneous access (femoral)

CP , Cardiac power; *IABP* , intra-aortic balloon pump; *LA* , left atrium; *LV* , left ventricle; *RA* , right atrium; *RV* , right ventricle; *VA-ECMO* , veno-arterial extra-corporeal membrane oxygenation.

Dysrhythmias and Pacing

Ventricular and supraventricular dysrhythmias are common. Close monitoring and treatment of electrolyte abnormalities may prevent dysrhythmias. New occurrences of complex ventricular dysrhythmias should stimulate a search for causal cardiac ischaemia and graft malfunction.

Ventricular fibrillation and pulseless ventricular tachycardia require rapid defibrillation, preferably before external cardiac massage, which may cause mechanical injury post-sternotomy. If haemodynamic stability cannot be rapidly restored, open cardiac massage should be instituted.

Facilities for atrioventricular pacing are essential as transient heart block is common.

All units should have regular training in life support protocols focused on the post-cardiac surgical patient. AF is the most common complication of cardiac surgery. [28] Its incidence varies from 10% to 40% in patients undergoing coronary artery surgery and up to 50% with some valvular procedures. Predisposing factors include a history of AF, valvular heart disease (especially mitral valve pathology), increasing age and prolonged P-wave duration. AF can be effectively treated and its recurrence prevented with intraoperative radiofrequency ablation and left atrial reduction during cardiac surgery [29] ; these may also provide a long-term survival benefit. [30] AF is probably less frequently observed following 'off-pump' surgery, and is most frequently encountered around the second and third postoperative days, but may occur weeks after surgery and hospital discharge.

AF is a potentially serious complication. Apart from discomfort, it may provoke or complicate haemodynamic instability. However, the major complication of AF is stroke, with an increased risk of approximately threefold. Based on echocardiography, there is the potential for embolic stroke within three days of onset of AF. AF is also associated with:

- increased inotrope usage
- increased use of IABP
- increased reoperation for bleeding
- prolonged ICU and hospital stay
- increased costs.

Several strategies are beneficial in preventing AF [31] :

- beta blockade
- amiodarone
- sotalol [32]
- diltiazem
- bi-atrial pacing
- dexamethasone
- colchicine [33]
- statins. [34]

Treatment of AF should be tempered with an understanding that spontaneous reversion to sinus rhythm is frequent. Early re-introduction of beta blockade, judicious fluid balance, avoidance of electrolyte imbalance, adequate control of pain and avoidance of hypoxaemia are associated with a reduced incidence of postoperative AF.[35] A treatment strategy is summarised in Table 73.3 .

Table 73.3

Whether rate control or rhythm control is unclear, with both strategies having similar complications and conversion rates.[36] Early cardioversion tends to be ineffective and potentially harmful. Although officially recommended in the presence of instability, this is not based on any empirical evidence.

Emergency Reoperation

Emergency re-sternotomy is indicated as part of resuscitation when haemodynamic stability cannot be rapidly re-established with conventional means. Patients who need emergency re-sternotomy generally suffer prolonged ICU stays and have higher mortality.[37]

Advantages compared with closed-chest resuscitation include:

- establishment of the cause of haemodynamic instability (e.g. tamponade and kinked graft)
- correction of the cause of haemodynamic instability
- more effective cardiac massage
- direct establishment of atrial and ventricular pacing.

Re-sternotomy also enables the re-establishment of cardiopulmonary bypass and regrafting, or correction of mechanical abnormalities as required. Infectious complications are probably increased by emergency re-sternotomy, but the incidence is not prohibitive.

A protocol specific to cardiac surgical units and an internationally recognised course are available.[38]

Other Complications

Coagulation

Excessive postoperative bleeding is a major cause of increased morbidity and mortality. Mechanisms are complex and include preoperative anticoagulation, thrombolysis and antiplatelet therapy, as well as activation of haemostatic mechanisms, including fibrinolysis.

A systematic approach to operative and postoperative blood conservation, including point-of-care testing to guide therapy, can significantly reduce bleeding, transfusion and resultant complications. [39] There is increasing evidence that transfusion is associated with excessive complications, including death, and that transfusion rates vary between institutions. [40]

Effective postoperative measures include reversal of residual heparin (including ‘heparin rebound’) and correction of coagulopathy with blood products. Re-transfusion of shed blood reduces autologous transfusion requirements without apparent side effects. A restrictive transfusion strategy can reduce exposure to transfusion without increased risk [41] ; restrictive transfusion to a Hb of 75 versus 90 g/L found no benefit in mortality or cost. [42]

Most studies of pharmacological strategies to minimise postoperative blood loss have involved preoperative or intraoperative interventions. Extrapolation to the postoperative phase is intuitive rather than established. Tranexamic acid reduces bleeding and exposure to blood and blood products. [43] Aprotinin was withdrawn from the market due to concerns of increased risk of adverse outcomes; however, it has now been reintroduced and registry data suggest no increased risk of serious complications associated with its use. [44] Desmopressin is probably less effective at reducing bleeding and has been associated with an increased risk of myocardial infarction. [45] Prothrombin complex concentrate provides a safe and effective alternative to fresh frozen plasma for the management of post-cardiopulmonary bypass coagulopathy. It is especially attractive in patients where circulatory overload is a concern, such as in the presence of RV impairment. [46] Activated factor VII may be effective in controlling bleeding, but may result in an increased risk of stroke. [47] ‘Off-pump’ surgery has been associated with excessive bleeding because of the administration of anticoagulant and antiplatelet therapy out of fear of early graft closure.

Respiratory

Postoperative mechanical ventilation remains routine in cardiac surgical patients. Immediate extubation appears to offer little patient benefit [48] ; similarly, neither does routine prolongation of ventilation. Extubation can be safely undertaken with simple protocols. Reintubation is rarely required but is more likely in older patients with pre-existing lung and vascular disease and impaired ventricular function. Reoperative surgery and bleeding requiring massive transfusion also increase the likelihood of early extubation failure.

Hypoxaemia is very common in the early postoperative period. It is mostly attributable to atelectasis as a consequence of cardiopulmonary bypass and intraoperative ventilation with high-inspired oxygen and repeated disconnection from the ventilator. Management strategies include lung protective measures, such as appropriate PEEP and lower tidal volume selection, prolonged inspiration time and careful recruitment of manoeuvres, probably valuable postoperatively due to the long periods of apnoea. Incentive spirometry and chest physiotherapy are commonly utilised in the postoperative period. Early mobilisation and the use of continuous positive airway pressure (CPAP) or high-flow nasal oxygen are commonly employed strategies. [49] Adequate analgesia facilitates physiotherapy and mobilisation. Non-steroidal agents may increase the risk of complications and are rarely used. [50] More concerning causes of hypoxaemia include severe heart failure and acute respiratory distress syndrome (ARDS). The aetiology of ARDS is diverse but includes shock, massive blood product administration and cardiopulmonary bypass itself. Management is not particular to this group of patients. Occasionally, profound hypoxaemia accompanies minor atelectasis with moderate pulmonary hypertension. Patent foramen ovale (which is seen in 10%–15% of the normal population) with right-to-left intracardiac shunt is the likely mechanism for this. Currently, there is much interest in oxygen, and specifically, whether hyperoxaemia or normoxaemia is most beneficial.

Studies in cardiac surgery of intraoperative and postoperative hyperoxaemia have shown no benefit and even possible harm.[51]

Clinically detected pulmonary embolism is an uncommon complication of cardiac surgery, probably due to bypass-induced platelet dysfunction, routine postoperative antiplatelet therapy and thromboprophylaxis.[52] However, asymptomatic thromboembolism may be significantly more common.[53], [54] Contrary to earlier beliefs, ‘off-pump’ surgery may not be associated with an increase in prothrombotic tendency or a need for a more aggressive thromboprophylaxis regimen.[55]

Pleural drains are not routinely inserted after valve surgery; however, when the mammary artery is harvested for bypass grafting, the pleura is breached, and thus pleural drains are placed. Once coagulation is normalised and drain output is less than 20 mL/h for 4 hours, the drains can be removed.

In patients with poor LV ejection fraction, pleural effusions may accumulate and limit ventilation. This often presents several days postoperatively, and if deemed necessary new pleural drains will need to be placed.

Diastolic dysfunction can be exposed following surgery when trying to wean a patient from the ventilator. As a result, the heart may fail on changing from positive to negative pressure ventilation, resulting in sudden onset pulmonary oedema. The reasons for this are an increase in venous return, an increase in work of breathing and oxygen demand, and catecholamine discharge during transition. In any patient who fails extubation, an echocardiogram is needed to assess diastolic function. Treatment options include avoiding tachycardia to allow LV filling, treat AF to allow atrial synchrony, fluid removal with diuresis and medical optimisation with ACE inhibitors.

Renal

Depending on its definition and the specific patient group, AKI is observed in 1%–5% of patients undergoing cardiac surgery. Risk factors include increasing age, heart failure, prolonged cardiopulmonary bypass, diabetes, pre-existing renal impairment and postoperative shock. Surgery without cardiopulmonary bypass may be relatively protective and other potentially modifiable factors include anaemia, blood transfusion and re-exploration.[56] Morbidity, mortality and costs are significantly increased in the presence of AKI. Effective preventive strategies, beyond careful haemodynamic management and minimising exposure to nephrotoxic insults, have not been established. Nevertheless, attention to urine output in the presence of known risk factors appears warranted.

The use of renal replacement therapy (RRT) is common to facilitate the normalisation of blood biochemistry. However, the optimal timing of when RRT should be commenced is unclear. Current research shows no benefits for early initiation of RRT[57]; however, due to the large intravenous fluid load cardiac patients receive, they may benefit from early intervention if the indication is fluid overloaded.

Neurological

Neurological complications of cardiac surgery include neuropsychiatric deterioration as a consequence of cardiopulmonary bypass, delirium and a range of peripheral neuropathies, the most frequent of which is unilateral phrenic nerve palsy. Paraplegia is a recognised complication of thoracic aortic surgery.

The most devastating neurological complication is cerebral infarction. The incidence varies with patient selection but ranges from 1% to 5%. The pathophysiology is mostly embolic. Risk factors include carotid artery stenosis, hypertension, AF, aortic atheroma, impaired ventricular function and peripheral vascular disease. ‘Off-pump’ and especially ‘anaortic’ surgery (no aortic manipulation) are protective,[58] and other operative techniques may also reduce the incidence.

Postoperative cognitive dysfunction is common, and multifactorial in nature. Standard intensive care measures include regular reorientation, minimising medications and investigating other causes, such as infection. Unless there is focal neurology, early imaging with either computed tomography or magnetic resonance imaging is not indicated.

Gastrointestinal

Gastrointestinal (GI) complications after cardiac surgery are rare (<1%). The commonest serious GI complication is mesenteric ischaemia which carries a high morbidity and mortality. [59] Risk factors include increased age, complex surgery and postoperative shock. The incidence of GI complications may be less with 'off-pump' surgery.

Mesenteric ischaemia secondary to atheromatous emboli, hypoperfusion and heparin-induced thrombocytopenia. An early postoperative rise in lactate level is common post-bypass; therefore detecting early mesenteric ischaemia is difficult. Any sign of abdominal pain should be investigated rapidly. Postoperative pseudo-obstruction and constipation are common. Perforation of the bowel or gallbladder, appendicitis and pancreatitis are rare but have been reported following cardiac surgery. Stress ulcer prophylaxis should be routine in this patient population until they are re-established on normal diets, which should happen as soon as possible following extubation.

Infection

Deep sternal wound infection is uncommon (0.5%–2.5%) but associated morbidity and mortality are significant. Risk factors have been variously reported but consistently include diabetes, obesity and the use of internal mammary arteries, especially if bilateral. Other contributing factors include prolonged surgery, chronic lung disease, male sex, low postoperative cardiac output, blood transfusion, sternal reopening and dialysis. Close control of blood sugar levels in diabetics [60] and preoperative nasal and oropharyngeal decontamination [61] may help prevent infection. Recently, mycobacterium chimaera has been identified as a contaminant of extra-corporeal heater-cooler units and should be considered in the case of unexplained early and persistent pyrexia.

Specific Procedures and Problems

Endocarditis Valvular Surgery

These patients may have acute or subacute presentation. They should be managed by a multi-disciplinary endocarditis team, including cardiac surgeons, cardiologists and microbiologists. Early organism identification can aid antibiotic selection and duration. Patients may present with embolic damage to organs such as kidneys, brain or gut which can be subclinical. Multi-organ dysfunction may ensue postoperatively requiring a high index of suspicion and careful monitoring in the ICU. If expedited surgery occurs, then there may be a massive inflammatory response with bleeding and hypotension. If it persists, a secondary source of infection must be sought through clinical and radiological examination.

Aortic Surgery

Aortic surgery involves a period of deep hypothermic circulatory arrest, which can be up to 30 minutes at 18°C. Patients should be carefully rewarmed in the operating theatre, and the avoidance of pyrexia is a key postoperative precaution. Active cooling may be considered to treat pyrexia. High arterial pressures should be avoided to minimise the risk of extending arterial intimal dissection; however, the maintenance of cerebral circulation must be considered. There is a high vascular complication rate in these patients with a mortality of 8%–15% and stroke rates of 7%–11%. Subtle long-term cognitive dysfunction is also common. [62]

Mitral and Tricuspid Valve Surgery

In high-income countries, surgery for mitral incompetence is more common, whereas mitral stenosis predominates in low and middle-income countries. Pulmonary hypertension, RV pressure overload and impairment and tricuspid valve regurgitation may develop with longstanding disease. These conditions significantly increase the risk of cardiac surgery; therefore expert management is demanded. Tricuspid valve repair with a de Vega suture or an annuloplasty ring is increasingly performed at the same time as left-sided surgery. The treatment of pulmonary hypertension with pulmonary vasodilators may be needed in addition to inotropic support of the right ventricle and appropriate ventilator settings. Monitoring with a PA catheter and phosphodiesterase inhibitors have a role here, but dose titration to avoid refractory hypotension is important.

Surgery for Hypertrophic Obstructive Cardiomyopathy

Patients with symptomatic hypertrophic obstructive cardiomyopathy can be offered surgical treatment when their disease is severe. A dynamic outflow obstruction in the LV outflow tract is often the underlying lesion. Surgery involves septal myectomy, which alleviates this obstruction and co-existing mitral regurgitation. Postoperative diastolic dysfunction is common in these patients and they do not tolerate AF well. In addition, inotropes are best avoided unless patients have end-stage heart failure. There is an increased risk of heart block and these patients may need permanent pacemakers.

Transcutaneous Aortic Valve Insertion

Transcutaneous aortic valve insertion (TAVI) initially evolved as a therapeutic option for aortic stenosis in patients who felt not to be medically fit for open surgery. This is often due to advanced age, LV dysfunction and multiple co-morbidities. Compared with medical therapy for those patients unable to have open surgery TAVI reduces mortality; however, there was an increase in stroke and vascular complications compared with open surgery.[63] More recently TAVI has been found to be non-inferior to surgery in terms of 1-year mortality in patients with severe symptomatic aortic stenosis and moderately increased operative risk.

In the ICU, these patients have a high risk of delirium. This is due to their premorbid state, the risk of other organ failure is raised and they may benefit from prolonged postoperative monitoring. As experience and indications increase, some of these patients will not necessarily need post-procedure critical care, but possibilities, such as TAVI in prosthetic valve procedures are likely to increase.

End-of-life Care

When severe complications occur following cardiac surgery that may significantly reduce the chances of patients making the expected postoperative recovery, this may give rise to conflict between teams. As the patient opted for surgery, consideration must be given to allowing ample time for recovery to occur; however, when severe complications, such as stroke, end-stage renal failure and failure to wean, occur, family discussions may arise around treatment limitation and withdrawal of care. It is important that the surgical team is involved in this dialogue and that the family is not given conflicting messages. Advice can be sought from palliative care teams when needed.

Post-operative thoracic surgical patient

Katrina Bramley, Shabana Anwar and Sofina Begum

Overview

Thoracic surgery provides speciality care for patients with disease or injury of the thorax, many of whom require surgical intervention to structures such as lung, chest wall, diaphragm, mediastinum, pleura, trachea or in some countries the oesophagus. In the United Kingdom, there are just over 25,000 thoracic surgical cases per annum, a high proportion are minimally invasive thoracoscopic techniques with increasing use of robotics. [1] Lung cancer resection represents nearly one-third of thoracic surgery workload, procedures include: lobectomy, segmentectomy, wedge resection and pneumonectomy. [2] The overall mortality for thoracic surgery is 1.2% with mortality relatively high in pneumonectomy patients (2.5%) when compared to lobectomy (0.9%). [3] The leading causes of mortality in post-lung resection patients are respiratory failure, sepsis then cardiovascular. [3]

Co-morbidities

Thoracic surgery patients represent an ageing group of often highly co-morbid patients with an increased risk of peri-operative complications. As age progresses frailty, chronic disease and cardiovascular co-morbidities tend to be more prevalent. Not only is tobacco smoking considered a major risk factor for the development of lung carcinoma, but it is also associated with significant respiratory and cardiovascular co-morbidities. For these reasons, patients presenting for thoracic surgery are commonly perceived as high risk requiring a multidisciplinary approach.

Critical Care Admission

Planned admission to critical care depends on the patient, surgery, hospital and healthcare system. In the United Kingdom, the majority of lung resection patients go to an enhanced recovery unit or high-dependency area post-operatively. A very small proportion of elective patients will have planned admission to intensive care, mostly those deemed very high risk or undergoing extensive surgical procedures such as large chest wall reconstructions, invasive mediastinal tumours and complex airways. The incidence of unplanned ICU admission after lung resection is 2.3% with an over-representation of patients having received an ‘open’ thoracotomy. [4] A large UK observational study of lung resection patients reported peak unplanned admissions on the day of surgery and days 2–3, median stay of 13 days and mortality in critical care of just over one-third. [4] The main reason cited for unplanned admission was respiratory failure. Other causes of unplanned admission include: bleeding, cardiac arrest, acute kidney injury, sepsis and airway complications. [4]

General Management Following Thoracic Surgery

Over recent years thoracic surgery has embraced enhanced recovery, the fundamentals of which have lowered morbidity and thus reduced hospital stay and cost. Points relevant to critical care encompass [5] :

- Thromboprophylaxis
- Opioid-sparing multi-modal analgesia
- Euvolaemic fluid management
- Early chest drain removal
- Avoidance of urinary catheters
- Early mobilisation
- Prevention of atrial fibrillation

Multi-Modal Analgesia

Multi-modal and effective analgesia is the cornerstone to peri-operative management allowing early mobilisation and reduction in respiratory complications. Pain from thoracic procedures particularly thoracotomy can be severe. Expert European consensus guidance strongly advocates minimising the use of opioids with the use of paracetamol and NSAID with a single shot or continuous catheter regional techniques such as paravertebral or erector spinae blocks. [6] Practice between Europe and the United States differs in terms of higher use of thoracic epidurals in the United States. [7]

Venous Thromboembolism Prophylaxis

Thoracic surgical patients are deemed at high risk for the development of venous thromboembolism due to the advancing age and many of the surgical interventions are for malignancy. United Kingdom and United States guidance recommend the use of mechanical prophylaxis from the point of admission to discharge. [5] Pharmacological prophylactic agents such as low molecular weight heparin or unfractionated heparin are routinely used for patients at low risk of bleeding complications. [5]

Fluid Management

Fluid management should aim for euvolaemia using balanced crystalloid due to the complex interaction of pre-existing lung disease, lung handling and reperfusion injury making the patients more prone to lung oedema and acute respiratory distress syndrome (ARDS). [5] Early oral intake is encouraged, as is the pre-emptive treatment of nausea and vomiting. In a euvolaemic patient with hypoperfusion, vasopressors are favoured rather than high-volume intravenous fluids unless the patient is actively bleeding. [5]

Chest Drain Management

Drains in the pleural cavity will be present post-operatively for most thoracic surgical procedures. While they are necessary, they are associated with pain, reduced mobility and a reduction in respiratory function hence should be removed at the earliest safe opportunity.[5] Digital drainage systems are increasing in use with the advantage of being easy to move, provide continuous suction and objectively measure the output of fluid and air. The role of drain suction versus non-suction continues to be debated; individual unit protocols are usually determined by surgical preference.

Specific Complications of Thoracic Surgery

1. Respiratory Complications

The most common cause of respiratory compromise is respiratory infection; the incidence of pneumonia is thought to be 5%–22% with an associated mortality of 19%–40%.[7] The combination of pre-existing respiratory pathology, major thoracic surgery and post-operative pain can lead to a vicious cycle; the inability to clear secretions, sputum retention and reduced lung expansion resulting in the development of atelectasis and chest infection which further compromises respiratory function. The preventative role of early mobilisation, physiotherapy and effective analgesia is paramount. Common pathogens include: Haemophilus, Streptococcal and to a lesser extent Pseudomonas and Serratia species.[8]

The development of ARDS in the post-lung resection patient is a dreaded complication with an associated high mortality. Incidence of ARDS is higher in the more extensive lung resections.[9], [10] Mortality is highest in pneumonectomy (50%) followed by lobectomy (42%) and then sublobar resection (22%).[10] Other risk factors include[9]:

- Inappropriate positive fluid balance
- Extent of tissue resection
- Duration of surgery
- Volume of blood loss
- Reoperation
- Uncontrolled drainage post pneumonectomy.

The intra-operative use of lung protective ventilation, PEEP and routine lung recruitment intraoperatively reduces the incidence of ARDS but cannot abolish the impact of one-lung ventilation, surgical trauma, lung manipulation and ischaemic reperfusion injury. [11] Supportive management and treatment of ARDS is the same as in any other critical care population.

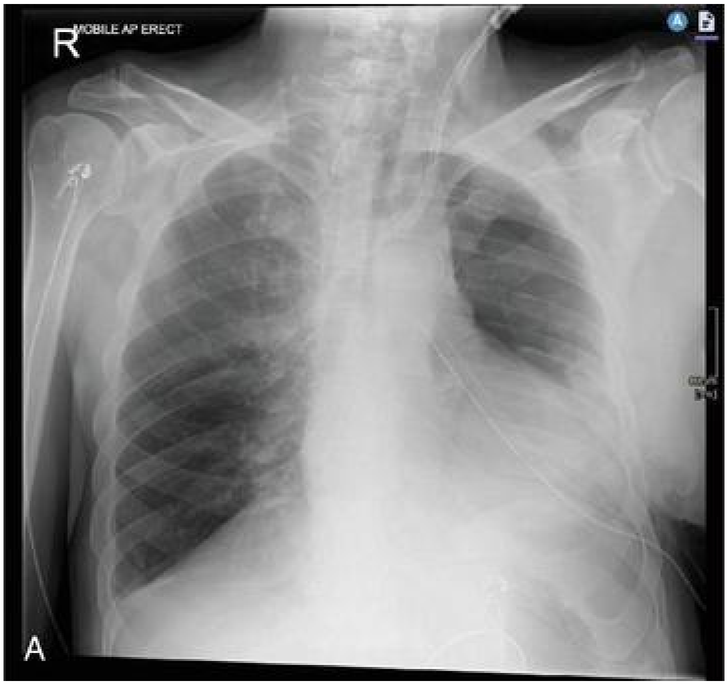
Lung cancer is more common in patients with pulmonary fibrosis compared to the general population. [12] In pulmonary fibrosis patients, not only is surgery associated with a higher incidence of respiratory complications, but rarely an acute inflammatory process can cause a severe and dramatic respiratory failure associated with an exceedingly high mortality. [12]

2. Cardiovascular complications

The reported incidence of major cardiac events in patients undergoing thoracic surgery is relatively high compared to other non-cardiac surgical specialities. [13] Atrial fibrillation (AF) is the most common cardiac peri-operative event with reported incidence between 10% and 40% peaking on days 2 to 4. [14] International guidance for AF management in stable thoracic surgical patients prioritises rate control with agents such as beta-blockers or amiodarone. [15-17] While amiodarone is considered safe in thoracic patients, it is important to be mindful of potential respiratory toxicity, particularly in pneumonectomy patients. [17] Anticoagulation in the context of AF should be individually considered with the benefits of reducing stroke outweighing bleeding risk. The incidence of peri-operative myocardial injury is approximately 9% in thoracic surgery patients. [18] There is an established link between lung resection and reduction of right ventricular function in the peri-operative period and beyond. Right ventricular dysfunction is an underdiagnosed pathology associated with significant mortality and morbidity. Vigilance is required to diagnose and meticulously manage right ventricular dysfunction. [19]

Additional Pneumonectomy Management

Despite pneumonectomy patients undergoing rigorous selection and pre-operative optimisation, they walk a fine line post-operatively requiring meticulous observation, early identification and aggressive management of complications. They should be nursed in a high sitting position and laterally tilted with the pneumonectomy side more downwards. Thoracic resections are more prone to ARDS and pulmonary oedema, additionally, in pneumonectomy patients, all the cardiac output is flowing through the existing lung temporarily increasing right ventricular and pulmonary artery pressures. [20] The pneumonectomy space is initially air filled, then over days to weeks will start to fill with fluid creating a fluid line (see Fig. 74.1A – C). Ultimately the pneumonectomy side will be fully fluid filled over weeks to months. Acutely the pneumonectomy space needs to be actively observed and managed. Rapid evacuation can lead to a mediastinal shift to the pneumonectomy side with resulting cardiovascular compromise or collapse. Conversely, rapid accumulation of fluid, for example haemorrhage, may cause mediastinal shift to the existing lung leading to respiratory compromise. To avoid these problems the drains are double clamped and actively managed through a process of controlled or ‘balanced’ drainage. Pneumonectomy patients have minimal respiratory reserve thus any complication should be aggressively managed. When using positive pressure ventilation particular care is required to maintain lung protective ventilation and manage the bronchial stump.



The set of four chest radiographs is arranged in a two-by-two grid. Each radiograph captures a frontal view of the thorax. The top left radiograph displays a centred cardiac silhouette with visible lung fields and ribs. The top right radiograph shows lung hyperlucency on the right side with an elevated diaphragm and gastric bubble. The bottom left radiograph includes medical lines and tubes, such as a nasogastric tube and monitoring leads. The bottom right radiograph displays multiple inserted lines, including what appears to be an endotracheal tube and cardiac monitor leads, with the thoracic cavity partially obscured by rotated positioning. All radiographs are marked with the letter R to denote orientation. One of the radiographs is labelled M O B I L E S E M I E R E C T at top left.

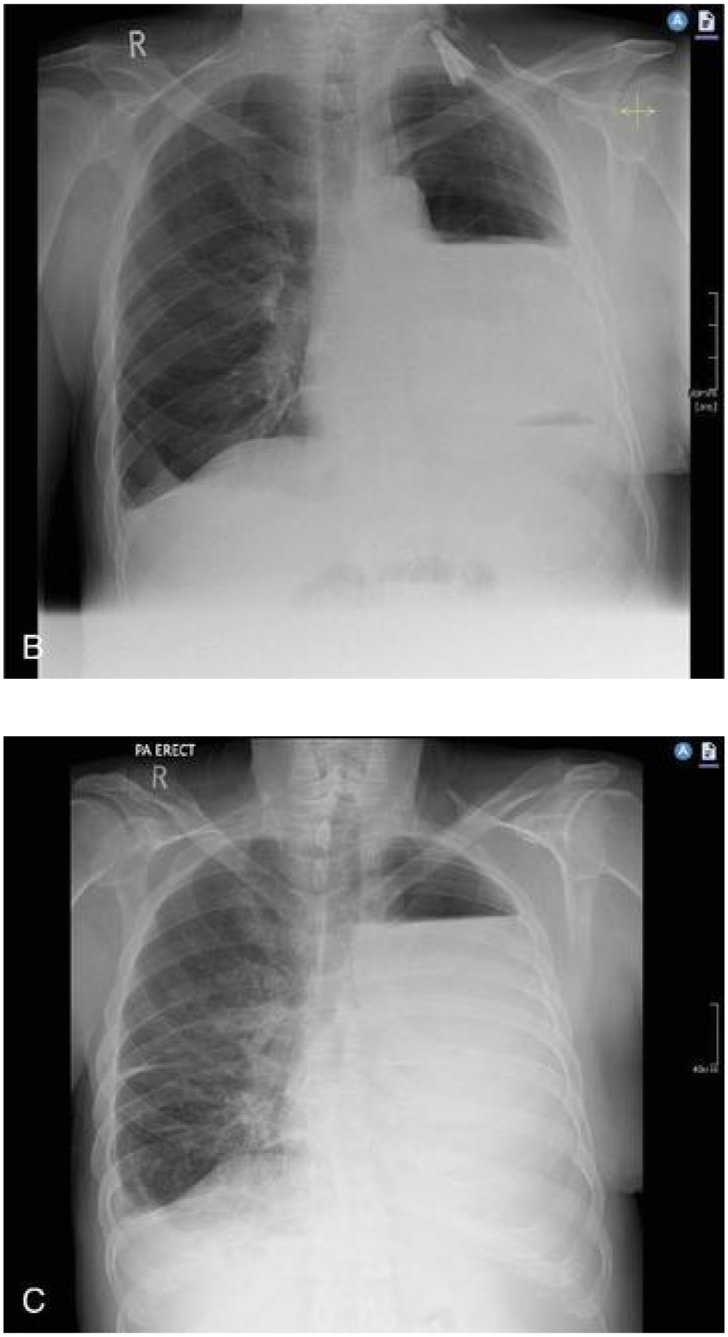


FIG. 74.1 Chest radiographs following a left pneumonectomy on post operative days 1 (A) and 3 (B), and at outpatient follow-up (C).

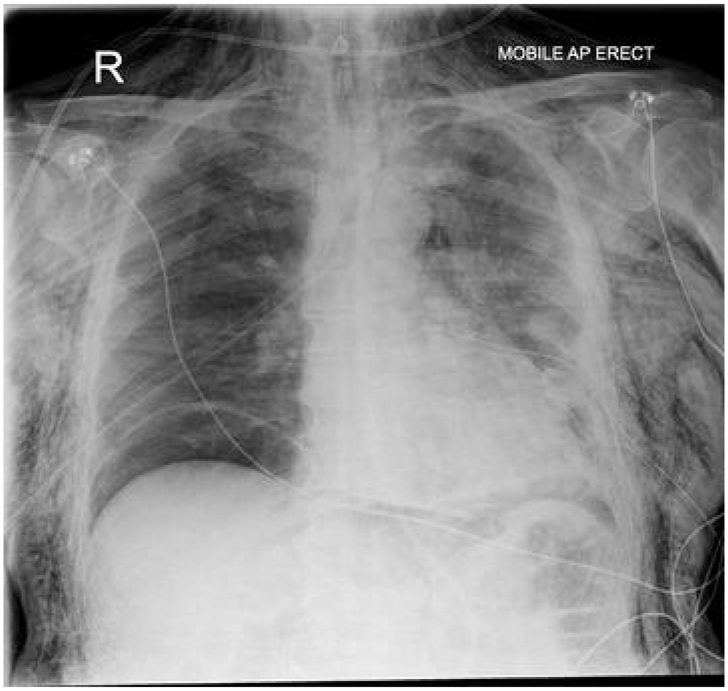
A rare acute complication of pneumonectomy involving pericardial resection is acute cardiac herniation when the cardiac structures herniate into the pneumonectomy cavity leading to cardiovascular collapse. [20] It is most likely to happen after a change in patient position, uncontrolled chest drain management or high airway pressures when mechanically ventilated. It is considered an emergency; the patient should be turned laterally with their pneumonectomy side uppermost with the aim of resolving circulatory collapse. The surgical team should be informed. In the rare incidence of cardiac arrest in a pneumonectomy patient, chest compressions may be less effective due to mediastinal shift – the heart may no longer be compressed between the sternum and vertebrae. [20]

Bronchopleural Fistula

Bronchopleural fistula (BPF) can be very challenging to manage in critical care and prolonged air leaks from BPF are consistently associated with a high morbidity (increased length of stay, pneumonia, empyema). [21-23] A BPF is a communication between the bronchial tree and the pleural space. While the literature often uses the umbrella term, 'bronchopleural fistula' to refer to both bronchopleural and alveolar-pleural fistula, these are anatomically distinct with a connection respectively between either the bronchial tree or alveolus with the pleural space. The continued passage of air from a bronchopleural or alveolar-pleural fistula into the pleural space is termed an 'air leak'. If this occurs beyond a 5–7 day period, it is considered to be a persistent air leak (PAL). [22] The presence of an air leak in the immediate period following thoracic surgery is relatively common with its incidence depreciating sequentially in the first four post-operative days with most having resolved by this point. [24], [25] Strong risk factors for PAL include: pre-existing lung disease, major anatomical lung resection and pleural adhesions. [26] The incidence of air leak is much higher in lung volume reduction surgery compared to other thoracic surgical procedures such as lobectomy and pneumonectomy (see Fig. 74.2). [24], [27], [28] Other causes of bronchopleural fistula can include: trauma, infection, barotrauma, iatrogenic injury, pneumothorax, lung cancer, inflammatory lung disease, empyema, radiotherapy and necrotising lung disease. [21], [22], [28]



The pair of chest radiographs taken in a mobile semi-erect position are displayed vertically. The top radiograph shows a frontal thoracic view with well-expanded lungs, visible ribs, and a clear cardiac silhouette, with medical lines and an endotracheal tube present on the right and left sides. The bottom radiograph, labelled MOBILE SEMIERECT with L marking on the upper left, also shows a frontal chest view with prominent rib structures and central mediastinum. Multiple medical lines including an endotracheal tube and monitoring leads are seen traversing both lung fields, and slight rotation is apparent.

FIG. 74.2 Chest radiograph showing an air leak.

Identification and Physiological Consequences

In the immediate post-operative period, an air leak can be objectively evidenced by: (1) Bubbling of the pleural drains in an underwater seal during expiration, forced expiration or cough (2) Calculated leak on a digital chest drain device (3) Presence of a differential between inspired and expired volumes on a ventilator. BPF presentation is variable from bubbling of a chest drain to the hyperacute tension pneumothorax or dramatic inability to ventilate a patient. In the absence of a functioning drain, a pneumothorax and/or subcutaneous emphysema will form. Diagnosis is gained by clinical examination paired with imaging such as a chest x-ray or CT. Subtle chest x-ray signs such as the flattening or reduction in the level of an established air/fluid interface can be easily missed. Physiological consequences of BPF include: incomplete expansion of the affected side, de-recruitment of the unaffected side, inability to maintain PEEP, empyema, systemic hypoxia and even death.

Management

The use of positive pressure ventilation, PEEP and increased frailty adds to the complexity of managing BPF. A simple air leak in a self-ventilating patient can rapidly transition to a challenging or life-threatening situation with positive pressure ventilation. While attention should be paid to the basic principles of critical care management, the bespoke management of BPF is dictated by the patient’s clinical condition, degree of urgency, aetiology and anatomical site. Patients with a large volume air leak or those with progressive increase in the volume of leak are more likely to require early definitive intervention. Unifying basic principles of BPF management include: limiting airflow via the fistula to promote healing, drainage of the pleural space and protection of the unaffected lung.

Alveolar-pleural air leaks are the most common.[22, 24] In the presence of a chest drain, these will often heal themselves with conservative management, time and patience.[22] Central BPF of the bronchus or segmental bronchi caused by surgical complications or trauma are more dramatic in presentation and troublesome to manage. If or when to intervene is one of the complexities of managing these patients. A large air leak, such as a suspected stump dehiscence warrants immediate surgical review. For continued air leak or failure of the lung to re-expand in spontaneous pneumothorax, international guidelines suggest surgical opinion should be invited from day 3–5 onwards.[29,30]

From a critical care stance, first methodically check the air leak is from the patient and not the breathing circuit, ventilator or dislodged chest drain, a so-called false air leak. Air leak flow via the BPF is proportional to the mean airway pressure. Reducing the peak gradient between the airways and pleural space will help reduce the driving pressure across the BPF. Strategies to promote air leak reduction or BPF resolution include[27,28]:

- Reduction in peak inspiratory pressure such as reducing tidal volume
- Reduction in peak end-expiratory pressure
- Reduced respiratory rate
- Tailored inspiratory time
- Promoting spontaneous ventilatory modes
- Early liberation from a ventilator

Medical management of BPF can be used for primary definitive management, for those in whom supportive management has been unsuccessful or as a bridge to definitive surgery.[21,22] Medical management can include pleurodesis or bronchoscopic techniques for the administration of glues, sealants, sclerosing agents or deployment of one-way valves (Fig. 74.3).[21,22] The use of one-way endobronchial or intrabronchial valves is relatively new with the Spiration IBV Valve System being licenced under the Humanitarian Exemption Program of the FDA in 2008 for the use of persistent air leaks in the post-operative surgical population (lobectomy, segmentectomy or lung volume reduction surgery).[31] Other one-way valves approved for the use of lung volume reduction in emphysema have been used ‘off-label’ for this purpose too. They are designed to allow air and secretions to be expelled out in expiration, not inspiration, reducing or ideally obliterating the air leak thus creating a more favourable environment for the BPF to heal or to progress ventilatory management. [32] They are licenced to be in situ for no longer than 6 weeks. [31] Complications can include: atelectasis, iatrogenic damage to the bronchial tree, bronchitis, infection distal to the IBV, device migration, persistent cough, pneumothorax and shortness of breath. [31]

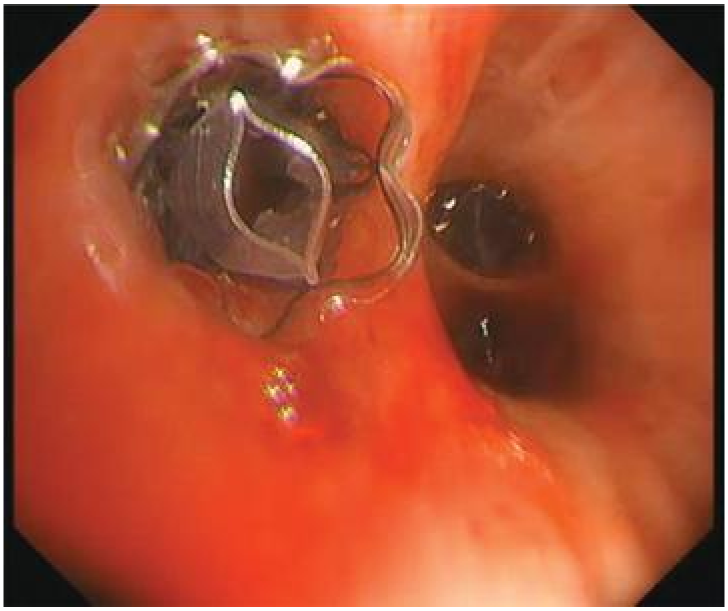


FIG. 74.3 Bronchoscopic image of a one-way valve.

Surgical management of BPF in critical care patients is likely to be high risk and potentially limited by the requirement for one-lung ventilation when proceeding to video-assisted thoracic surgery (VATS) or thoracotomy. Surgical intervention can be for treatment or the consequences of BPF including [22] :

- Repair of bronchial stump
- Resection of blebs/bullae
- Pleurodesis: chemical or mechanical (pleural stripping)
- Placement of tracheal or bronchial stents for occlusion of stump dehiscence as a temporising measure prior to definitive surgery
- Empyema drainage ± decortication

The inability to ventilate and/or oxygenate a patient due to a large leak is an emergency. Air will pass down the path of least resistance, in a large BPF this will be from the ventilator to the drain via the BPF. This can be further exacerbated by the unaffected lung being non-compliant so a path of relative resistance compared to the BPF side. A tension pneumothorax must be immediately decompressed. If simple changes to ventilation are unsuccessful the only options are either lung isolation or extracorporeal life support (ECLS). A single lumen endotracheal tube in the bronchus of the unaffected non-BPF side can be used as a rescue technique by isolating the BPF from the ventilator thus stopping the air leak. The use of a double-lumen endotracheal tube or bronchial blocker should be reserved for those familiar with the technique such as a cardiothoracic anaesthetist. A double-lumen tube has the advantage of isolation and potential independent lung ventilation but the disadvantage of unfamiliarity in critical care and smaller inner diameter which causes challenges when wanting to undertake complex bronchoscopy procedures. [28]

Life-threatening Haemoptysis

The most severe cases of haemoptysis, those with massive or life-threatening haemoptysis, have a quoted mortality of 9%–38%. [33] There is no consensus on the definition of massive haemoptysis; pragmatically it is life-threatening haemoptysis sufficient to cause either abnormal gas exchange, airway compromise or cardiovascular instability. [33], [34] Typically, this would encompass haemoptysis volumes of 100 mL/h to over 500 mL per 24 hours. The aetiology of life-threatening haemoptysis encompasses a vast range of pathologies, the most frequently seen causes include bronchiectasis, lung carcinoma and cavitating lung infections such as tuberculosis or aspergillosis. [33] Clinically it is important to distinguish whether the source of bleeding is from the respiratory tract or from structures above the vocal cords or gastrointestinal tract. The origin of life-threatening haemoptysis is likely to be from the bronchial artery circulation which is at systemic pressure. Chronic infection or inflammation of the lung modifies these vessels rendering the patient at higher risk of haemoptysis from dilated arteries, new vessels or collaterals. Rarer causes can originate from the formation of non-bronchial artery collaterals in chronic inflammation, for example aorta, intercostals, subclavian and internal mammary arteries or from the pulmonary arteries themselves.

Management

The patient should be resuscitated with a methodical approach prioritising airway and oxygenation in tandem with volume resuscitation and correction of any coagulopathy. Activation of a 'massive haemorrhage protocol' can be useful. If known, place the side of bleeding downwards in a lateral position to help protect the 'good' side. The expectoration of large volumes of bright red blood can be quite frightening for both the patient and clinician, patients are often very anxious requiring reassurance. Intubation for airway control or ensuing respiratory failure may be required, preferentially with a single lumen endotracheal tube size 8.0 or larger which will take a flexible bronchoscope with ease. The single lumen tube can either be placed in the trachea to ventilate both lungs or endo-bronchially (right or left main bronchus) to temporarily isolate the bleeding lung to gain control and avoid soiling of the non-bleeding side. Other methods of isolation include double-lumen endotracheal tubes and bronchial blockers. While the double-lumen tube has the advantage of lung isolation, the internal diameters of the tracheal and bronchial lumens are smaller thus making clot removal more difficult and being potentially restrictive to bronchoscopic interventions. The use of non-invasive ventilation during an active bleed should be avoided.

Tranexamic acid (TXA), an antifibrinolytic is often used. While there is little evidence specifically in life-threatening haemoptysis, there is a large evidence base for its use in other sources of major haemorrhage. A Cochrane review of the use of tranexamic acid in haemoptysis found it reduced the bleeding time but not the incidence at seven days. [35]

The localisation of the point of bleeding is important, to guide where intervention can be undertaken and potentially provide diagnosis. The choice of modality will be dependent on the patient's clinical status, safety of transfer and skill availability. Choices include: chest x-ray, CT, angiography and bronchoscopy. CT imaging is far superior to a chest x-ray for identifying the site in life-threatening haemoptysis. Bronchoscopy and chest x-ray have the advantage of portability to the bedside. While bronchoscopy has been shown to be successful at identifying the site of bleeding and has the advantage of removing clots or intervention, it is not as diagnostic as CT. [33]

In most cases of life-threatening haemoptysis, bronchial artery embolisation (BAE) has superseded the use of immediate bronchoscopy for direct therapeutic intervention with the aim of sourcing and stopping the bleeding. Interventional radiologists exhibit great skill in navigating endovascular catheters, usually via femoral puncture, through often complex vasculature searching for the source of bleeding to deploy their embolisation material. Conscious, non-sedated patients will commonly complain of transient chest discomfort or dysphagia during the embolisation. [33] There are distinct risks of BAE including unintentional embolisation of spinal arteries with profound neurological consequences. BAE has been reported to provide immediate success in a high proportion of patients although some patients will require multiple procedures. [33] Immediate success does not necessarily equate to prolonged success with 10%–58% having a recurrent episode of haemoptysis. [33] Even if the embolisation has been successful, a large clot burden can remain in the bronchial tree thus some centres will review the need for rigid bronchoscopy and removal of clot at 24–48 hours post embolisation.

Flexible bronchoscopy still has a role in identifying the site of bleeding or for intervention. Its timing can be controversial in terms of early versus delayed and needs to be considered on an individual basis. The usual indications are either because BAE is not suitable or has failed. Although lacking in evidence, endobronchial instillation of epinephrine, tranexamic acid or cold saline is used. Other bronchoscopic techniques include: balloon isolation, laser, argon plasma coagulation and stent insertion. It can be quite hard to suction up large clots via the long thin lumen of a flexible bronchoscope, rigid bronchoscopy performed by a thoracic surgeon is advantageous for the removal of high clot burden and good visualisation of the proximal airways. Beyond rigid bronchoscopy, surgical intervention during an episode of massive haemoptysis is unusual, mainly due to the success of BAE. Indications for emergent surgery in massive haemoptysis include: traumatic injury to the thorax, iatrogenic pulmonary artery rupture, pulmonary artery haemorrhage caused by resectable lung cancer or inability to perform BAE safely. [33]

A rare cause of life-threatening haemoptysis in critical care is a tracheo-arterial fistula in tracheostomy patients. Life-threatening haemoptysis from a tracheostomy should be assumed to be a tracheo-innominate fistula until proven otherwise. [36] These are associated with pressure necrosis from high cuff pressures, mucosal trauma, chronic steroid use, high innominate artery and low placed tracheostomy. [36] Patients will often have a sentinel bleed prior to the major event. In addition to the management already discussed, techniques should be attempted to tamponade the bleed prior to definitive surgical management, these include: over-inflating the tracheostomy cuff, digital compression or inserting an endotracheal tube via the tracheostomy in controlled circumstances.

For a small number of patients, palliative care may be deemed the most appropriate management. Patient-centred care will involve supportive measures and anticipatory medicine planning with agents such as benzodiazepines for anxiolysis and opiates for pain or cough suppression in the event of a life-threatening or catastrophic haemoptysis.

The Use of Extracorporeal Life Support in Thoracic Surgery

Extracorporeal life support (ECLS) can be used in thoracic surgery for supporting the respiratory and/or cardiovascular systems. Inevitably a proportion with ECLS used in the peri-operative period will require continued support or weaning in critical care. [37], [38] Some of these patient groups would be considered controversial with high associated mortality requiring individual decision making. [38] Outside of lung transplantation, there are three main groups of thoracic surgical patients utilising ECLS:

1. Treatment of potentially reversible complications after thoracic surgery such as ARDS and pneumonia.
2. Peri-operative ECLS in complex thoracic surgery particularly airway procedures.

(3) Patients with existing severe respiratory failure such as ARDS requiring thoracic surgery.

Management of the post-operative neurosurgical patient

Judith Bellapart, Rosalind L. Jeffree and Alan Coulthard

Introduction

Patients recovering from intracranial procedures are commonly admitted to neurosurgical intensive care units (ICUs) or high-dependency units for close observation. These procedures generally have low complication rates, but unrecognised complications may have devastating consequences. Goals of ICU care in this population include the use of optimal monitoring strategies as well as general and specific management principles for post-operative care.

Principles of Management of Neurosurgical Patients

The role of intensive care management of post-operative neurosurgical patients is primarily directed at identifying post-operative complications. [1] However, neurological deterioration in this group may manifest with very minor symptoms, and so there is the risk that either complication may be identified late, or patients may be exposed to over-prescription of adjuvant investigations such as computerised tomography (CT) and analogues. The concept of ‘neuro-worsening’ (defined as a decline of at least 2 points on the motor score of the Glasgow Coma Scale (GCS), a new-onset lack of pupillary reactivity or the development of pupillary asymmetry of 2 or more mm from baseline) introduced by the Conscious Trials investigators,[2–4] has standardised definitions, with the aim of rationalising management.

In addition, the use of post-operative checklists, endorsed by the World Health Organisation (WHO), the Scottish Intercollegiate Guidelines Network (SIGN) and the Royal College of Anaesthetists (RCoA) has become a standard of care[5],[6] in certain jurisdictions[7],[8]; although these are not globally applied. Furthermore, there is evidence of a positive impact on neurological outcomes by allocating post-operative patients to neuro-specific units[9] where trained nurses may apply specific protocols.[10] Identifying which patients can be safely managed outside of an ICU has shown to be a cost-effective approach[11–14] but a hybrid model may be required to maintain real-time monitoring and more regular observations for the purpose of identifying patients' deteriorations promptly.

Initial Management

On admission to the ICU, a standard approach to a post-operative patient should be taken, including:

- Handover: An accurate neurosurgical and anaesthetic handover, including a review of surgical notes, intra-operative events and post-operative plan.
- Clinical assessment: A complete clinical examination on arrival to the ICU has the purpose of establishing a clinical baseline and matching expectations against the surgical procedure and intra-operative anaesthetic status.
- Review of background history to identify comorbidities that may impact post-operative progress.
- Rationalising which baseline medications must be continued, and which are contraindicated in the immediate post-operative phase (i.e. anti-coagulants and anti-platelet agents).

Generic care requires the following considerations:

- Maintaining airway patency. Patients following certain neurosurgical procedures are at risk of airway obstruction. Multiple causes may be involved, such as local post-operative oedema following anterior cervical spine stabilisation; impaired breathing pattern secondary to brainstem injury or compression after posterior fossa surgery; reduced level of consciousness with or without motor deficits in supratentorial procedures. These limitations may be compounded by the development of neurogenic pulmonary oedema or cardiovascular instability. Furthermore, the development of hypoxia or hypercapnia can represent a secondary insult with implications for neurological progress.
- Ensuring appropriate ventilation during the intra-operative phase has been assessed in a post-hoc analysis of the Multicentre Local ASsessment of VEntilatory management during General Anaesthesia for Surgery study (LAS VEGAS) [15] in which a low tidal volume/low Positive End Expiratory Pressure (PEEP) strategy and the inclusion of recruitment manoeuvres were not related to post-operative pulmonary complications in this specific population. Furthermore, the use of PEEP (at higher than physiological levels) has been shown to be safe without increasing intracranial pressure (ICP) or compromising cerebral perfusion pressure (CPP). [16]
- Allowing a ‘head up position’ (Fowler position) when possible: semi-recumbent position has been shown to minimise the risk of ventilation and non-ventilation acquired pneumonia by reducing micro-aspirations. In addition, this position enhances cerebral venous drainage minimising the risk of hyperaemia, increased cerebral blood volume and subsequent ICP. [17]
- Being aware of the presence of post-craniectomy pain in the first 48–72h following surgery is important, as this has been underrated. [18] A few standardised pain assessment tools such as the Behavioural Pain Scale (BPS), the Critical Care Pain Observation Tool (CPOT) and the Nociception Coma Scale-Revised (NCS-R) have been described, also for ventilated patients or those with altered levels of consciousness, but their use remains low. [19], [20] Opioids are the most used analgesics however their use is

associated with oversedation, respiratory depression, hypercapnia and secondary increased ICP which can confound clinical assessment. Enhanced Recovery After Surgery (ERAS) protocols have been validated, standardised and applied for different types of surgical disciplines. They were established with the intention to improve patients’ recovery and functional status soon after surgery. ERAS protocols have been adopted and shown to reduce hospital length of stay and improve outcomes. [21] There is evidence to suggest that multimodal analgesia can have clinical benefits, specifically by applying the ERAS protocol. [22]

- Minimising post-operative nausea and vomiting, which may have a prevalence of up to 40%–50%. [23] Prophylaxis is usually indicated, specifically following posterior fossa craniotomy or in patients with surgery or haemorrhage near the obex (the junction of the fourth ventricle and central spinal canal). A randomised controlled trial reported that droperidol was more effective than ondansetron [24] when used at non-sedating doses.
- Surveillance for presence of post-operative seizures. A consensus statement published in 2000 stated that routine prophylaxis was not recommended and if used, it would require discontinuation after the first-week post-surgery on those patients that were seizure-free. [25] More recent Cochrane reviews on the use of anti-epileptic drugs (AED) for supratentorial and infratentorial non-traumatic craniectomy on patients who have had no seizures and have no previous exposure to AED, remain controversial [26], [27] showing no outcome benefit on the prophylactic use of AED. The most updated Cochrane review, [28] reported very limited and low evidence supporting AEDs for the prevention of early and late post-craniectomy seizures, although there was substantial heterogeneity amongst the compared trials.
- Management of hemodynamic instability related to autonomic dysfunction or hyper-sympathetic drive. Supratentorial structures, such as cortical and subcortical regions, the hypothalamus, the insula, the amygdala and the anterior cingulate gyrus in combination with the brainstem, contribute to the control of the

autonomic nervous system. [29] Hypertension following neurosurgery may increase the risk of post-operative haemorrhage, vasogenic oedema or Posterior Reversible Encephalopathy Syndrome (PRES). [30] Current practice regarding blood pressure control in this population is extrapolated from the thresholds described in the INTERACT 2 (*aggressive BPs <140 mm Hg within the 1st hour of admission*) and ATACH 2 trials (*aggressive control versus a standard threshold of BPs 140–179 mm Hg within the first 2 hours and maintained through 24h*). [31–33] A Blood Pressure-Attained-Analysis of the ATACH 2 trial by Qureshi et al. [34] raised safety concerns of end-organ adverse events derived from a rapid achievement and attainment of blood pressure reduction, suggesting that further studies are required. More recently, the Interact III Trial [35] supports the care bundle that focuses on the correction of blood pressure, hyperglycaemia, hyperthermia and coagulopathy, during the acute management of patients with haemorrhagic stroke, although the external validity of this trial is debated. In the interim, whilst the use of nitrate derivates for the treatment of hypertension has traditionally been a focus of debate amongst patients with head injury and increased ICP [36–39] due to the potential detrimental effects of vasodilation and cerebral hyperaemia, the ENOS trial has showed safety in a cohort of non-head injury patients with ischaemic and haemorrhagic stroke. [40] Furthermore, evidence of the reduction of nitrate levels in cerebrospinal fluid (CSF) and cerebral dialysate fluids following head injury, has been linked to the reduction of cerebral microcirculation leading to the hypothetical use of nitrate derivates as biomarkers and therapeutic options. [41]

- Maintaining a high level of surveillance for intracranial bleeding, as it is a foreseeable and life-threatening complication. Bleeding most commonly occurs within the first hours following surgery and amongst patients with cerebral amyloid angiopathy, thrombopenia, coagulopathy, hyperaemia, preoperative treatments with anti-platelet or anti-coagulants and certain surgical procedures such as incompletely resected tumour or resection of arterio-venous malformation.[42] Remote bleeding from the surgical site is commonly located at the cerebellum and it is attributed to the loss of cerebrospinal fluid (CSF) pressure with subsequent cerebral hypotension, cerebral ‘sagging’ and transient occlusion of cerebellar veins leading to venous infarction and bleed.[43] A posterior fossa bleed is a life-threatening emergency as brainstem compression may occur very quickly, so a high level of awareness is required.

- Anticipation of the development and potential complications of swelling. Unlike cytogenic oedema, cerebral vasogenic oedema responds to steroids,[44] but a plateau effect is often seen after 4–6 days post-surgery. Dexamethasone is the recommended steroid because of its low mineralocorticoid effect. Beyond that time, the secondary effects of steroid treatment may outweigh the benefits.
- Prevention of the development of deep venous thrombosis (DVT), as neurosurgical patients have a higher risk than other populations. Following international guidelines, in the absence of contraindications, pharmacological prophylaxis should be instituted within 72 hours post-surgery.[45]
- Pre- and intra-operative antibiotics have been shown to reduce surgical site infection in craniotomy patients[46] but the use of post-operative antibiotics is controversial and not supported by any high-quality studies. The most significant risk factor for post-operative infections is the presence of a CSF leak.[47, 48] In patients with an external ventricular drain (EVD), the development of ventriculitis is associated with a higher morbidity and mortality. Ventriculitis secondary to infection with gram-negative bacilli, including multi-resistant organisms is increasing over time. The lack of established diagnostic criteria and the absence of standardised treatment regimens make the design of high-quality studies difficult. A recent review established the risk factors for ventriculitis as well as outlining a series of diagnostic and therapeutic approaches.[49]
- Neurosurgical patients often develop sodium-water dysregulation. Accurate diagnosis of the underlying process is essential to

facilitate appropriate management. The differential diagnosis of hyponatraemic states requires the interpretation of paired blood and urine analysis prior to the initiation of hyperosmolar treatment, an estimation of the total body water and the net loss of sodium. However, the diagnosis of 'cerebral salt wasting' has been overstated; often pressure-induced polyuria or hyperosmolar polyuria are underlying contributors, therefore its accurate diagnosis requires adherence to the Halperin criteria, as shown in Box 75.1 .[50] Diabetes insipidus, defined as polyuria, urinary specificity gravity of 1 and a urinary hypo-osmolality must be recognised to avoid intravascular contraction and rapidly evolving hypernatraemia. Knowledge of the type and volume of fluid administered during surgery is essential. Finally, the correction of dysnatraemia requires caution to avoid pontine myelinolysis or cerebral oedema, respectively.[51]

- Traumatic or post-operative pneumocephalus is common and can persist for days; in such situations, the anaesthetic use of nitrous oxide is contraindicated as it could increase ICP even further.[52, 53] Recognition of tension pneumocephalus is a life-threatening emergency. Two classic radiological features can indicate tension pneumocephalus: 'the Mount Fuji' sign (*air depressing and widening the inter-hemispheric space*) as shown in Fig. 75.1 and 'the air bubble' sign (*multiple small bubbles scattered into several cisterns*) as shown in Fig. 75.2 , often associated with rapid neurological decline.[54] This is a neurosurgical emergency requiring surgical intervention. Less severe symptomatic pneumocephalus can be improved by high-flow oxygen[55] or hyperbaric oxygen.[56] As nitrogen absorption is inversely proportional to the partial pressure of oxygen in blood, with high oxygen concentration the intracranial nitrogen absorption gradient increases whilst being replaced by oxygen which is more soluble. Other management strategies include patient positioning to 30 degrees (Fowler position) and avoiding Valsalva manoeuvres.[57]
- Maintaining appropriate levels of glycaemia according to site-specific practice is important. Hyperglycaemia has been associated

with worsened neurological outcomes, so protocolised glucose control is required [58], [59]; however, studies utilising micro-dialysis in head injury patients have shown that tight glucose control is associated with energy depletion responses, so avoiding episodes of hypoglycaemia is essential. [60]

- Being aware of the presence of a CSF leak, which can be expected following trans-sphenoidal pituitary surgery or can become a *de novo* development. This condition increases the risk of meningo-encephalitis, but there is no consensus regarding prophylactic antibiotic coverage. CSF can be identified by the presence of glucose and beta-trace proteins such as Beta-2 Transferrin (a highly specific and sensitive test) although false positives may occur in chronic renal failure. Leakage of clear fluid in a high-risk case should be presumed to be a CSF leak and managed as such without waiting for beta-trace protein results.
- Personalised management of delirium. A recent systematic review in post neuro-surgical delirium has reported an incidence of 20% [61] compounded by premorbid cognitive dysfunction and the underlying neurological disease. In addition, common determinants are the type of cortical incision, the retraction of cerebral lobes, the use of electrocautery, the presence of localised bleeding or oedema and direct brain injury, factors leading to neuro-inflammation and blood-brain barrier disruption. When prescribing antipsychotic medications consideration should be given to the patient’s regular medication schedule as this may influence the choice of drug. Flexible and frequent visits by the patient’s family have been associated with reduced delirium without increasing other ICU complications. [62]
- Management of paroxysmal sympathetic hyperactivity [63] when present. This is a syndrome accompanying cerebral swelling and characterised by waves of hyper-sympathetic responses such as tachycardia, hypertension, hyperthermia and hyperventilation. It can resemble withdrawal states or situations of inadequate analgesia. A variety of pharmacological strategies such as non-

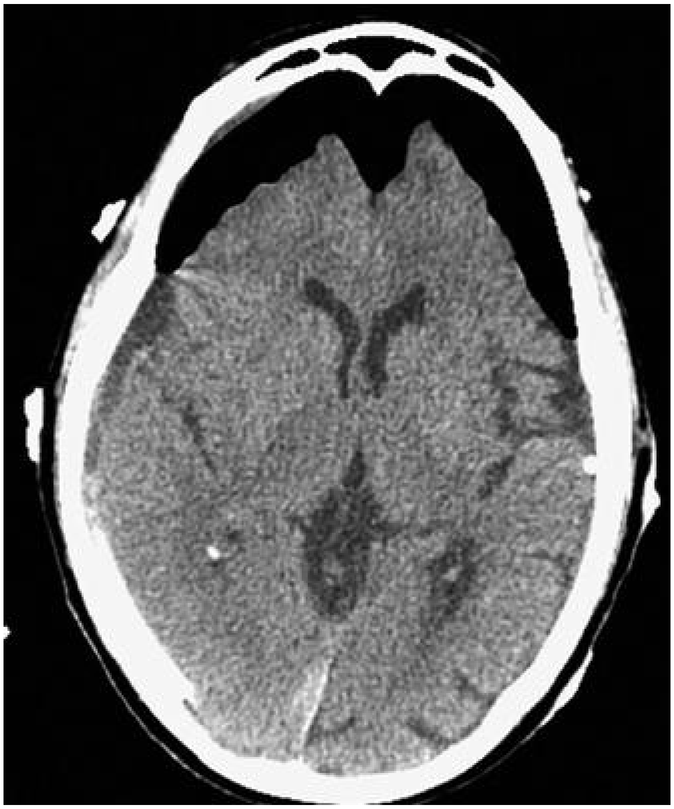
selective beta blockers, opioids, short-acting benzodiazepines, GABA and alpha-2 agonists can be used.

Box 75.1

The diagnosis of CSW is one of exclusion. There must be an intracerabral lesion and the excretion of Na^+ and Cl^- without another obvious cause

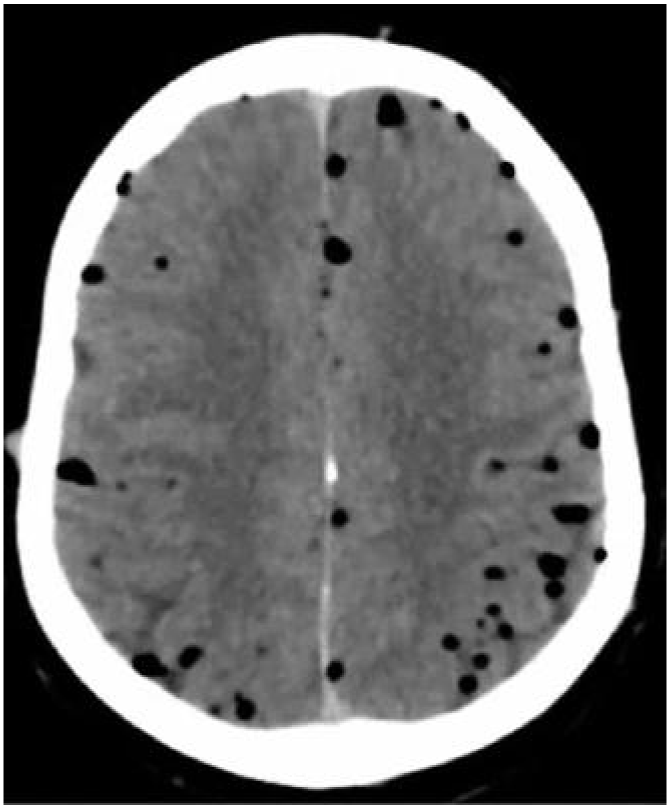
1. The following must be ruled out
    - A physiologic cause for the excretion of Na^+ and Cl^- (e.g. an expanded ECF volume)
    - A noncerebral cause for the natriuresis
        - Exogenous diuretic administration
        - Pseudo-diuretic-like states
            - States with low aldosterone action [39]
            - Bartter syndrome; Gitelman syndrome
            - Ligands for the calcium receptor in the Henle loop, such as hypercalcaemia and cationic drugs (e.g. gentamicin) and possibly, cationic proteins, such as in multiple myeloma
        - Obligation of Na^+ excretion by the excretion of anions other than Cl^-
        - High output renal failure
2. Possible explanations for salt wasting in patients with a CNS lesion
    - Natriuretic agents of cerebral origin
    - Down-regulation of renal Na^+ transport by chronic ECF volume expansion
    - Pressure natriuresis (e.g. adrenergic hormone overload)
    - Suppression of the release of aldosterone

CNS , central nervous system; *CSW* , cerebral salt wasting; *ECF* , extracellular fluid.



The C T scan of the brain shows an axial view with a large asymmetric area of low density in the left cerebral hemisphere. The left lateral ventricle appears compressed, and there is a midline shift toward the right. The sulci on the left side appear effaced compared to the right side. The right lateral ventricle is mildly dilated. The surrounding bone structures of the skull are intact.

FIG. 75.1 Mount fuji sign.



The C T scan of the brain in axial view shows multiple well-defined round areas of air density distributed across both cerebral hemispheres. These areas appear as dark circular voids of varying sizes, more numerous along the cortical regions. The midline structures are preserved. No significant mass effect or midline shift is observed. The bone structures appear intact and symmetrical.

FIG. 75.2 Radiological signs of tension pneumocephalus.

Neurological Monitoring in Neurosurgical Patients

The use of multimodal monitoring can enable early identification of developing complications, although clinical trials of these modalities have yet to demonstrate a clinical outcome benefit.

- Regular and real-time neurological assessment is essential for the purpose of establishing a baseline to compare with and identify immediate changes. The use of standardised scoring systems has historically promoted the use of the GCS [64] and the Full Outline of Unresponsiveness (FOUR score), introduced to bypass the limiting verbal component of the GCS and by introducing brainstem reflexes. [65] An additional midbrain (pupillary reactivity) monitoring tool has now been introduced. Pupillometers are very sensitive, and their application detects and anticipates increases in ICP. [66]
- Cardiovascular and respiratory monitoring are core practices for critically ill patients. Continuous recording of oxygen saturations (SpO_2) informs about systemic oxygenation, but in the damaged regions of the brain, there is an increased oxygen diffusion gradient which increases the risk of cerebral ischaemia. Moreover, the arterial partial pressure of CO_2 is a major determinant in cerebral vasoreactivity and vessel diameter. End-tidal CO_2 ($ETCO_2$) monitoring amongst ventilated neurosurgical patients is not just standard safety monitoring but also an essential determinant of cerebral blood flow (CBF).

A more detailed treatment of neuromonitoring, including ICP monitoring, real-time autoregulation monitoring to define optimal CPP and brain tissue oxygenation is given in Chapter 64 .

Specific considerations : the care of elective neurosurgical patients also includes certain pathology-specific aspects.

- Transfusion thresholds amongst neurocritical care patients have been the focus of various multicentre trials in both, the traumatic brain injury (TBI) and subarachnoid haemorrhage (SAH) populations. Within two decades following the Transfusion Requirements in Critical Care trial, [67] multiple micro-dialysis studies reported the harm of sustained anaemia during the acute phase of moderate and severe TBI. Significant accumulated evidence has built equipoise around transfusion practices. Currently, debate focusing on transfusion thresholds and optimisation of $PTiO_2$ amongst TBI has led to the BOOST-3 [68] and BONANZA trials which are currently recruiting. [69] Amongst SAH patients, the SAHARA trial [70] has focused on rheology, microcirculation and delivery of oxygen, specifically amongst patients in vasospasm. However, elective neurosurgical patients fall outside of the scope of these trials, therefore optimal haemoglobin level remains at the intensivist's discretion.

- Surgery for different tumour diagnoses and locations entails risks specific to the underlying neuroanatomy and pathophysiology and these should be discussed with the surgeon. Steroids are often indicated to control vasogenic oedema and help with post-operative nausea and pain. The dose is controversial, but evidence suggests that 4 mg dexamethasone daily is as effective as higher steroid doses, but with fewer side effects. [71] Prophylactic anticonvulsants are not recommended in patients who have not had a seizure. [72]
- Patients during the post-operative phase of trans-sphenoidal or pituitary procedures are at risk of developing hypocortisolism, hypopituitarism and diabetes insipidus (DI). The management and correction of each specific disorder may be case specific. These patients are also at risk of visual loss as the first sign of impending complication so visual fields and acuity should be included in their regular neurological observations.
- Patients who have had angiographic neuro-interventional radiology procedures have foreseeable risks specific to their intervention. Blood pressure control may be paramount, especially in cases of arterio-venous malformation reduction. In addition, patients with elective coiling or endovascular stents, have a higher risk of micro-thrombosis often with an associated morbidity, may require the use of anticoagulation during the first 12 hours post-procedure. Whilst there are no international guidelines, site-specific protocols guide towards the type of anticoagulation (low molecular versus

unfractionated heparin), or platelet anti-aggregation (with protocolised platelet inhibition monitoring) strategies used. Point-of-care (POC) testing to inform of the anticoagulation and anti-aggregation strategy used are available for clinical decision making.

These patients are also susceptible to the development of contrast-induced encephalopathy. This process has unclear pathophysiology, although it has been reported that patients with hypertension, renal failure and those receiving high dose of ionised contrast are at higher risk. Symptoms can have a short onset following the procedure and it can show focal or globalised deficits. The likely pathophysiology is related to disruption of the blood-brain barrier and subsequent neuronal excitability. Early recognition and supportive management are required, as it can spontaneously resolve in days. [73]

- Following posterior fossa surgery and due to its limited compliance, even a small volume bleed or a mild degree of swelling, can cause posterior fossa hypertension leading to a herniation syndrome. The presence of an EVD which releases pressure from a supratentorial compartment may not avoid posterior fossa hypertension specifically in situations of obstructive hydrocephalus. Progression to irreversible brainstem compression may not be appreciated without a thorough neurological examination, including limb reflexes, tone and brainstem reflexes. The assessment of brainstem reflexes incorporated into the neurological examination, is essential.

  Often, during posterior fossa surgery patients are positioned for prolonged time in a prone position, increasing the risk of glottic swelling which may compromise post-surgical extubation. For those patients who return to ICU still intubated, assessment of their readiness for extubation must include their capacity to cough, gag and protect their airway.

Postoperative care after major abdominal operations

Janet Liang and Ywain Thomas Lawrey

Introduction

The intent of this chapter is to discuss important aspects of the interface between intensive care unit (ICU) and surgical management for postoperative care, rather than medically oriented issues that form part of standard ICU management. The topics covered include ICU therapies in the context of the postoperative patient with organ failure, perioperative surgical interventions requiring management while in ICU and details about selected abdominal operations.

ICU Organ Support After Abdominal Surgery

Respiratory Issues

Postoperative pulmonary complications frequently occur after abdominal surgery and are often multifactorial. Chandler et al. [1] reported an incidence of 2.0% to 5.6% in the general surgical population and up to 20% to 70% in the upper abdominal and thoracic surgery population. Arozullah et al. [2] proposed a broad definition, including '…hypoxia, atelectasis, bronchospasm, pulmonary infection, pulmonary infiltrate, aspiration pneumonitis, acute respiratory distress syndrome, pleural effusions and pulmonary oedema…'. Risk factors include those patient related (e.g. age, frailty and chronic disease), operation related (e.g. operating time[3] and incision proximity to the thorax) and anaesthetic related.[4] Thoracoabdominal operations, for example oesophagectomies and aortic aneurysm repair (thoracic and abdominal) are particularly high risk for postoperative pulmonary complications.[5] Treatment is multifocal and supportive.[4]

Two postoperative pulmonary complications will be discussed in further detail because although abdominal operations increase their likelihood in general, they may have underlying causes which may complicate ICU management.

Pleural Effusions

Pleural effusions are often associated with major abdominal operations, although the effusions rarely cause critical deterioration by themselves alone. Transudates may occur due to fluid movement from the abdomen to the thoracic cavity, or volume overload from fluid resuscitation and/or low plasma oncotic pressure due to hypoalbuminemia from malnutrition. Exudates may occur due to the underlying disease leading to the operation, or an operative complication. Chylothorax is a rare but important cause of pleural effusion, which can be either a transudate or exudate but is defined by a high chylomicron level. It occurs due to thoracic duct damage, in thoracoabdominal operations or by CVL insertion. Whichever the cause, the decision on if and by what technique the effusion is drained usually depends on the size and content of the effusion and its impact on respiratory mechanics.[6]

Pulmonary Embolus and Other Venous Thromboembolism

The incidence of venous thromboembolism (VTE) after major abdominal surgery is low, although if it occurs the mortality rate is significant. VTE may only become apparent after a patient's ICU stay. While risk stratification scores can more precisely define individual patient risk, VTE prophylaxis of some type should be given to patients post-abdominal surgery, even if only mechanical prophylaxis, for example compression stockings. [7] Low molecular weight heparin appears to be more effective as prophylaxis after abdominal operations than unfractionated heparin [8] and there is evidence that the former is also associated with a lower heparin-induced thrombocytopenia risk. [9] It is more challenging where the patient is thought to be at risk of bleeding, and yet requires full dose anticoagulation for treatment of thrombotic events. Examples would be pulmonary embolism and uncommonly, portal vein thrombosis. [10] The latter can complicate hepatobiliary procedures and can cause septic shock due to mesenteric ischaemia. Ultimately, clinical management of such patients needs to be considered on an individual basis.

Mechanical Ventilation

ICU is sometimes called to consider ventilatory support for actual or potential postoperative respiratory failure. Only a minority of patients should need to be admitted into the ICU directly after their abdominal operation for invasive ventilation in the absence of shock. [11] However, if they are then extubated and reintubated, this is associated with significant mortality. Thille et al. [12] proposed that high-flow nasal cannulas (HFNC) in extubated patients, plus non-invasive ventilation (NIV) in extubated patients thought to be at high risk of reintubation, should be used as preventative measures immediately post extubation to decrease the likelihood of respiratory deterioration. They should not be used as a means to delay reintubation if respiratory failure still occurs. If NIV is used after postoperative respiratory failure has occurred, there is presently no evidence that it improves mortality. [13] It may improve oxygenation and ICU length of stay, without increasing the risk of anastomotic leaks, inclusive of thoracoabdominal procedures. It is unclear what settings and duration of NIV are optimal. [13]

The need for postoperative invasive mechanical ventilation is usually related to the indication for and findings of the abdominal operation, as well as preoperative patient morbidities. [14] Clinical concern about the patient's perceived preoperative risk and tolerance of emergent operations may also contribute to requests for postoperative continuation of invasive mechanical ventilation, [15] as can a likely need for imminent re-operation. If prolonged (>96 hours) mechanical ventilation is required, elderly patients who have had high-risk surgery will have a significantly increased likelihood of mortality and decreased quality of life. [16]

Renal Issues

Perioperative acute kidney injury (AKI) is associated with increased hospital mortality and length of stay, plus an increased risk of chronic kidney disease. [17] Abdominal surgery is in itself a risk factor for AKI, [18] although, in this clinical context, other risk factors are often present. Perioperative events which are risk factors include hypovolaemia and usage of nephrotoxins, for example IV contrast for radiological investigations. Abdominal aortic operations, especially emergency ones, have a particularly high AKI incidence. [19] Intraabdominal hypertension is a risk factor for AKI, though laparoscopic surgery via pneumoperitoneum has not been shown to be a clear risk factor. [20] Post renal obstruction should also be considered as a rare, but still possible cause or contributor to AKI. This may range from the easy to address, for example a blocked urinary catheter, to the more complex, for example ureteric injury or blocked ureteric stents in colorectal surgery. [21]

AKI markers are often imperfect due to many reasons. Urine output and serum creatinine are commonly used, despite being known to not necessarily be reliable in the postoperative setting. Postoperative oliguria is common due to the combined effects of hypovolaemia, cardiovascular instability, increased catecholamine and hormone levels and the effects of general and regional anaesthesia. Usage of diuretics and irregular vital sign monitoring may further complicate the usage of urine output as an indicator of kidney injury. Biomarkers are not used routinely in clinical practice at present. [22]

There is no definitive research on the optimal timing or dose of renal replacement therapy in critically ill patients after abdominal operations, although it is possible that starting renal replacement therapy early if it is required could improve patient outcomes. [22]

Analgesia

Systemic opioids are usually the main analgesic for ICU patients. This can be problematic after abdominal operations, given opioids are significant factors in causing ileus. Epidurals that use local anaesthetic accelerate gastrointestinal transit return yet are unlikely to increase the risk of anastomotic leak. [23] Unfortunately, the effect against ileus may be limited. [24] Epidural disadvantages include potential hypotension and issues regarding the timing of catheter insertion and removal if anticoagulants are being given. Abdominal fascial plane blocks avoid the disadvantages of epidurals, for example hypotension and decreased mobility due to motor block, but may not cover visceral or pelvic pain. [25]

Nutrition

Nutrition timing is dependent on the patient's pre-existing nutritional state and what their underlying abdominal pathophysiology is. Generally, if a patient is malnourished preoperatively, or is expected to be unable to maintain above 50% of the recommended intake for more than seven days, feeding should be started as soon as possible postoperatively. Patients who were well nourished preoperatively and who are expected to absorb sufficient nutrients orally can have feeding deferred for up to seven days.

Compared to parenteral nutrition (PN), enteral nutrition (EN) decreases infectious complications and ICU length of stay, although it does not affect overall mortality. Therefore, EN should be attempted first in adult critically ill patients where the gut is functioning. [26] There is no evidence that early EN, that is, within 24 hours after colorectal surgery [27] or within 1 to 7 days after upper gastrointestinal cancer surgery [28] increases postoperative complications, including anastomotic leak or aspiration. This includes oesophagectomy for oesophageal cancer, [29] gastrectomy [30] and pancreatic surgery for cancer. [31] However, patients requiring vasopressor support for shock should have gradual EN commencement and it should be delayed in patients requiring active resuscitation. [32] PN should be reserved for those patients not meeting nutritional requirements by EN. Choosing between gastric tube feeding versus post-pyloric feeding, the latter is associated with a lower incidence of aspiration and faster achievement of nutrition targets.[33] There is no significant mortality difference between the two EN modes.

Ileus

Postoperative prolonged ileus is a frequent postoperative complication of abdominal surgery, caused by intraoperative gut handling and ensuing inflammatory responses.[34] Typically, it starts within the first postoperative week. While it most commonly occurs in bowel surgery, it can also occur after abdominal vascular and urological operations, and in laparoscopic abdominal surgery. Therapeutic approaches are aimed at preventing it or supportive treatment after it has occurred.

Surgical Interventions

Drains and Management

After insertion, the surgical team should label the drain position and whether low vacuum suction is required. They should also let the ICU team know if drainage fluid samples are required, and what is being looked, for example microbiological for intraabdominal collection, or biochemical such as creatinine (at urinary concentration) for urine leakage, amylase for pancreatic fistula. Drain biofilm may interfere with a correct microbiological diagnosis in older drains.[35]

The usage of drains can be generally divided into prophylactic and therapeutic. Prophylactic abdominal drain usage is generally decreasing except perhaps in some pancreatic and colorectal operations. Therapeutic usage is still indicated to drain infected collections, as part of source control. Such drains may be surgically or percutaneously inserted. Drains may be used to manage smaller anastomotic leaks, by converting them into isolated enterocutaneous fistulas. If the fistula flow gradually decreases and the patient improves, the drain can be shortened and/or removed. Sudden reduction of fistula flow may be associated with abscess formation and lingering abdominal sepsis.

Stomas

Stoma issues that concern ICU clinicians are most often the early complications of stomal ischaemia/necrosis, and fluid/electrolyte loss.

Stoma ischaemia/necrosis may require surgical revision. While stromal oedema is common postoperatively due to mesenteric venous congestion, this should resolve relatively quickly. Signs of ischaemia usually start within 24 hours of operation. The decision for surgical revision depends on the length of necrosis; if it extends below the fascia, surgical revision will be required. [36] Other stomal problems that may require surgical revision during an ICU stay are stomal retraction, which can cause faecal leakage into the abdomen and stomal stenosis causing bowel obstruction.

Stoma fluid loss is usually more problematic with ileostomies rather than colostomies, given the extra facility for fluid reabsorption in the latter. Ileostomies usually function within 24 hours of formation and normally produce about 400 to 1400 mL/day. [37] A stoma producing over output over 1000 to 2000 mL/day is defined as high output, [36] and may be caused by bowel obstruction, drugs or sepsis. Apart from requiring fluid and electrolyte replacement, this will likely also interfere with EN. Antimotility agents can be used to decrease stoma flow.

Urostomies facilitate urinary diversion in patients who require radical cystectomy or who have significant bladder dysfunction for other reasons. [38] Early complications include urinary tract infection and those like other bowel operations, including anastomotic leak, bowel obstruction and ileus.

Flaps

Flaps such as the vertical rectus abdominis myocutaneous flap can be used in both major elective pelvic operations or in major acute pelvic operations, for example Fournier’s gangrene, to cover large perineal tissue deficits. These often require specific attention to maintain adequate perfusion for flap survival and as a potential source of infection. It is important to detect if flaps are inadequately perfused because they can then still be salvaged by surgical exploration and microanastomotic revision. If flap failure does occur, it tends to do so within three days of initial operation. [39]

Special Surgical Contexts to Consider for the Intensivist

Intraabdominal Hypertension and the Abdominal Compartment Syndrome

Normal intraabdominal pressure in critically ill adult patients is usually about 5–7 mm Hg, although it can be up to twice this in obese patients. [40] Intraabdominal hypertension is defined as an ongoing increase in intraabdominal pressure equal to or above 12 mm Hg due to pathological causes. Abdominal compartment syndrome (ACS) is defined as an ongoing intraabdominal pressure above 20 mm Hg associated with new organ dysfunction. [41] ACS can be either primary (due to intraperitoneal or retroperitoneal causes, for example bleeding and sepsis) or secondary (extraperitoneal causes, for example bowel oedema from massive fluid resuscitation or extra abdominal due to decreased abdominal wall compliance, for example burns). It is also possible to have recurrent ACS, even with an open abdomen. [41] Patients at high risk of ACS include those with pancreatitis, post orthotopic liver transplant and post-abdominal aortic surgery [42] and those patients who have had excessive fluid resuscitation. [40]

Pathophysiology caused by ACS involves multiple organ systems:

- decreased pulmonary compliance and increased airway pressure due to cephalad pressure on the diaphragm;
- hypotension and decreased cardiac output due to decreased venous return leading to decreased preload, and increased afterload from increased systemic vascular resistance in intraabdominal arteries;
- renal dysfunction resulting from both decreased renal blood flow secondary from decreased cardiac output and a direct effect from intraabdominal hypertension;
- impairment of hepatic blood flow associated with raised lactate, separate from any effect of decreased cardiac output. [43]

It is thus unsurprising that ACS is associated with a significant mortality rate. [42]

ACS detection requires clinical suspicion and regular testing of intraabdominal pressure, as the clinical examination is not sensitive or specific. [44] Intravesical pressure by fluid instillation into the bladder and subsequent manometer measurement is most used as it is simple, cheap and easy to repeat. The patient should be supine, with a relaxed abdominal wall, and no more than 25 mL of fluid should be instilled as larger amounts of fluid may iatrogenically raise the pressure. [43] It is difficult to achieve these conditions consistently in patients who are not mechanically ventilated and sedated, given the pathophysiology of ACS. Kirkpatrick et al. [41] suggested a measurement frequency of at least four hourly, albeit eight hourly has been argued to be more pragmatic. [45] Where intravesical pressure measurement is contraindicated or unreliable, that is, due to bladder trauma, intraabdominal or pelvic packing or post cystectomy, other techniques exist including inferior vena cava or intragastric pressure measurement. [43]

ACS Management

Supportive interventions consist of reducing bowel contents (e.g. nasogastric insertion), removing intraabdominal masses as appropriate, improving abdominal wall compliance (e.g. neuromuscular blockade in the invasively ventilated and sedated patient) and optimising fluid management. [41] When intraabdominal hypertension is over 20 mm Hg and there is new organ dysfunction, this is unlikely to be enough and surgical abdominal decompression i.e. the open abdomen is strongly suggested. [41]

The Open Abdomen

An open abdomen which the surgeon has deliberately deferred fascial closure after having opened the abdominal cavity. [46] Indications include ACS, or as part of damage control surgery, for example for massive bleeding, or as a staged part of managing severe intraabdominal sepsis, especially if the septic source has not been found on the first laparotomy. The latter two indications can also devolve later in their course to ACS. An open abdomen should not be lightly undertaken, as it is very resource heavy on surgical and ICU teams and can lead to early complications of intraabdominal infections and gastrointestinal fistulae.[47] Other specific patient care issues for the intensivist are the need for careful fluid control and nursing care of the negative pressure wound therapies which are now often used to temporarily close the abdomen. From the surgical perspective, abdominal fascial closure will be aimed for as early as it is safe to do so. This is ideally within seven days, to avoid later complications, for example frozen abdomen, entero-atmospheric fistulas.[48]

Mesenteric Ischaemia

Intestinal ischaemia occurs when blood flow through the mesenteric circulation is insufficient for the intestine’s metabolic demands. Acute intestinal ischaemia is associated with a high mortality rate and is usually caused by acute mesenteric embolus or thrombus.[49] Non-occlusive disease, for example vasculitides, strangulated gut and hypoperfusion due to shock as a cause is less usual, as is mesenteric venous thrombus. Although rare, intestinal ischaemia can develop after surgery. After aortic surgery, the causes are typically thromboembolic or mechanical obstruction of mesenteric blood flow.

The diagnosis of acute mesenteric ischaemia can be particularly challenging, as the initial presentation may be non-specific prior to deterioration into septic shock. Acute abdominal pain, particularly that out of proportion to the clinical examination, is its most frequent symptom. There are no accurate and specific biochemical tests available for the detection of early, reversible mesenteric ischaemia.[50] Lactate has also often been used to judge therapeutic response and prognosis, although it is a poor marker for the detection of surgical complications.[51] D lactate, the second stereo isomer of lactate, and other biomarkers may be more useful mesenteric ischaemia biomarkers although they are not commonly used at present.[50] Urgent CT angiography with contrast is recommended on any suspicion of mesenteric ischaemia. Early diagnosis improves patient outcomes.[49] Resuscitation, antibiotics and urgent laparotomy to resect non-viable bowel and re-establish vascular flow would be the usual next steps in management.[52]

Enterocutaneous Fistulae

An enterocutaneous fistula (ECF) is an abnormal communication between the intraabdominal gastrointestinal tract and the skin. ECFs are usually classified by anatomy and source, output, and underlying cause. [53] ECFs most commonly result from previous abdominal operations, although they can also result from inflammatory bowel disease, cancer, and intraabdominal infections. [54] Their major management issues are the high frequency of associated sepsis, high fluid and electrolyte and nutrition supplementation requirements and the need for attentive wound care to prevent skin breakdown. [55] EN is still preferable where possible, either alone or supplemented with PN. [54] Medications such as somatostatin can be used to attempt to expedite spontaneous ECF closure, albeit these are not replacements for the primary supportive interventions.

Intraabdominal Sepsis Including Source Control

Quick detection, rapid commencement of appropriate antibiotic cover, surgical source control and supportive care are all vital for the management of intraabdominal sepsis. Surgical source control and adequate antibiotic coverage are the only modifiable mortality risk factors for patients admitted to an ICU with complex intraabdominal infections. [56]

Source control consists of measures to remove the infection source and to control ongoing contamination. That this is rapid and effective is vital for critically ill patients, [57] whether this is achieved by surgery or by percutaneous means. Percutaneous or endoscopic drainage is increasingly becoming the first line source control for abdominal abscesses. [58] Also, novel endoscopic approaches have been developed, for example trans colonic, transrectal and trans gastric for other anatomic locations. Laparotomy or laparoscopy is still likely to be required where this will not be enough, for example complex or multifocal abscesses, and those associated with large anastomotic or visceral leaks. Patients with ongoing intraabdominal sepsis may benefit from initial damage control surgery followed by relook laparotomy, which can be made easier by the open abdomen approach. [59]

Bariatric Operations

Elective bariatric operations only occasionally require ICU management. If complications such as bleeding, anastomotic leak or obstruction do occur, emergent re-operation will often be required. In that event, mechanical ventilation and ICU length of stay are likely to be prolonged compared to non-bariatric patients. Fistulas are the most common postoperative surgical complications, although operation site bleeding and small bowel obstruction can also occur. [60] Anastomotic leaks, particularly if they require re-operation or are detected late, are associated with poor outcomes. [61]

Malnutrition is a risk factor for poor hospital outcomes in obese patients. The ‘obesity paradox’ suggests that patients who are overweight or moderately obese are more likely to survive than patients with normal or more severe obesity in certain clinical contexts, including the general adult ICU population. [62] However, when malnutrition is also considered, obese malnourished patients have worse hospital outcomes than those obese patients without. [63] Malnutrition detection and management for the obese is lacking. [64] Assessment is often more challenging, for example for sarcopenia, [65] and there is no consensus on the estimation of energy and protein requirements. [66] In the absence of definitive research, Dickerson et al. [64] recommended a pragmatic approach adapted to the individual patient, using, in general, a higher protein and lower calorie content for both enteral and PN.

Whipple Procedure

The Whipple procedure (pancreaticoduodenectomy) is performed for cancers in the pancreatic head, ampulla, duodenum, distal bile duct and chronic pancreatitis. [67] Mortality rates have decreased with time, although morbidity is still common. The most common local complications are delayed gastric emptying and pancreatic enteric leak. The latter often results in abscess or fistula formation, but its effects may not become apparent until after the immediate postoperative period. [68] Post pancreatectomy haemorrhage is relatively rare and typically late but is associated with a high mortality rate if it occurs. [68] It is also possible rarely to have biliary complications, being leaks early on and strictures later. [69]

Oesophagectomy

The surgical approach for oesophagectomy was traditionally the Ivor-Lewis operation (laparotomy and right thoracotomy) with an intrathoracic anastomosis or the McKeown operation involving three operative fields and with a cervical anastomosis. [70] Grimminger et al. [71] noted that while cervical anastomoses were associated with higher leakage rates, they also may have a lower mortality risk. Further operative modifications have been made to improve postoperative outcomes from these two basic types. This includes modification into minimally invasive oesophagectomy which involves a hybrid approach – thoracoscopy or laparoscopy combined with an open approach in the other operative field. [72]

The most feared complication of oesophagectomy is anastomotic leak or fistula, which significantly increases mortality risk and worsens long-term outcomes. Anastomotic leaks can present in a range of acuity from no clinical signs to septic shock. Factors affecting the presentation include where the anastomosis is (cervical or thoracic), and how big and contained the leak is. [73] Common systemic signs are respiratory impairment, arrhythmias and atrial fibrillation, in particular, other cardiovascular instability or decline in mentation. [71], [74] Chest pain, persistent cough, abnormal drain output and other signs suggestive of mediastinitis can point to intrathoracic leakage. [73] Clinicians must therefore have a low threshold for investigation for leaks, to enable prompt decision-making about investigation and intervention.

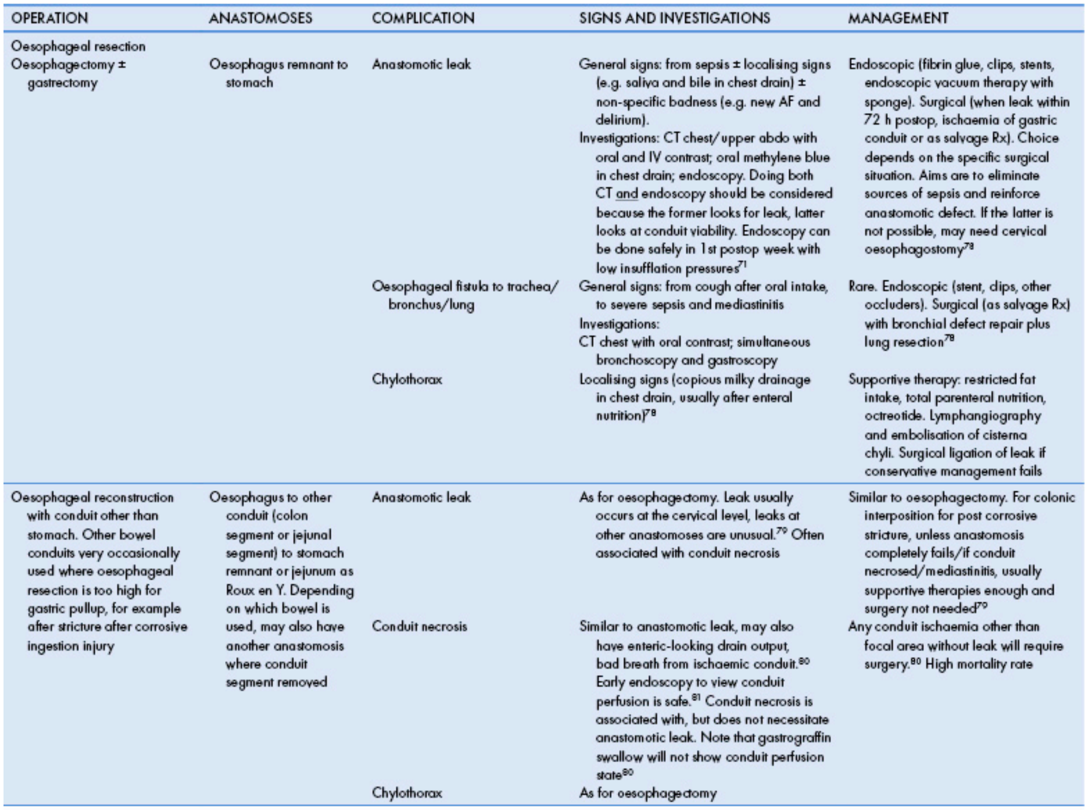
If a leak is suspected, both endoscopy and CT scan should be considered as the former assesses conduit viability, while the latter can identify collections and the state of the lungs. While endoscopy needs to be done carefully with low insufflation pressures, it can be done safely without causing patient deterioration in the first week postoperatively. [71] Management techniques have evolved, with endoscopic interventions including stents and endoscopic vacuum therapy now being used before or instead of re-operation depending on the specific surgical situation. [71] Supportive care remains important in any event.

Pelvic Exenteration

Pelvic exenteration was originally performed as a palliative procedure for advanced cervical cancer and has gradually evolved to become a potentially curative operation for patients with cancer of multiple origins in the pelvis, especially advanced or locally recurrent colorectal cancer. [75] Associated mortality rates are relatively low, although morbidity is still common. The most common urologically are urine infections or urine leaks which are asymptomatic and often diagnosed late. [76] The term ‘empty pelvis syndrome’ is used to describe complications arising from the cavity caused by the removal of pelvic organs and includes pelvic collections, small bowel fistulae or adhesions and perineal wound breakdown. Surgical innovations to counter this include using the patient’s own tissue, for example as flaps or even artificial intrapelvic prostheses. [77] Major postoperative bleeding seldom occurs.

Complications After Major Abdominal Operations

- The following focuses on complications more likely to cause significant patient deterioration, either during the postoperative operative stay or that causing patient readmission to the ICU.
- Any of the following operations can be complicated by wound infection, internal fluid collections and abscesses and internal damage to adjacent organs.
- Laparoscopic or laparoscopic-assisted techniques are common and may contribute to the following complications by additional early damage to blood vessels and viscera.



OPERATION	ANASTOMOSES	COMPLICATION	SIGNS AND INVESTIGATIONS	MANAGEMENT
Oesophageal resection Oesophagectomy ± gastrectomy	Oesophagus remnant to stomach	Anastomotic leak	General signs: from sepsis ± localising signs (e.g. saliva and bile in chest drain) ± non-specific badness (e.g. new AF and delirium). Investigations: CT chest/ upper abdo with oral and IV contrast; oral methylene blue in chest drain; endoscopy. Doing both CT and endoscopy should be considered because the former looks for leak, latter looks at conduit viability. Endoscopy can be done safely in 1st postop week with low insufflation pressures[71]	Endoscopic (fibrin glue, clips, stents, endoscopic vacuum therapy with sponge). Surgical (when leak within 72 h postop, ischaemia of gastric conduit or as salvage Rx). Choice depends on the specific surgical situation. Aims are to eliminate sources of sepsis and reinforce anastomotic defect. If the latter is not possible, may need cervical oesophagostomy[78]
		Oesophageal fistula to trachea/ bronchus/lung	General signs: from cough after oral intake, to severe sepsis and mediastinitis Investigations: CT chest with oral contrast; simultaneous bronchoscopy and gastroscopy	Rare. Endoscopic (stent, clips, other occluders). Surgical (as salvage Rx) with bronchial defect repair plus lung resection[78]
		Chylothorax	Localising signs (copious milky drainage in chest drain, usually after enteral nutrition)[78]	Supportive therapy: restricted fat intake, total parenteral nutrition, octreotide. Lymphangiography and embolisation of cisterna chyli. Surgical ligation of leak if conservative management fails
Oesophageal reconstruction with conduit other than stomach. Other bowel conduits very occasionally used where oesophageal resection is too high for gastric pullup, for example after stricture after corrosive ingestion injury	Oesophagus to other conduit (colon segment or jejunal segment) to stomach remnant or jejunum as Roux en Y. Depending on which bowel is used, may also have another anastomosis where conduit segment removed	Anastomotic leak	As for oesophagectomy. Leak usually occurs at the cervical level, leaks at other anastomoses are unusual.[79] Often associated with conduit necrosis	Similar to oesophagectomy. For colonic interposition for post corrosive stricture, unless anastomosis completely fails/if conduit necrosed/mediastinitis, usually supportive therapies enough and surgery not needed[79]
		Conduit necrosis	Similar to anastomotic leak, may also have enteric-looking drain output, bad breath from ischaemic conduit.[80] Early endoscopy to view conduit perfusion is safe.[81] Conduit necrosis is associated with, but does not necessitate anastomotic leak. Note that gastrograffin swallow will not show conduit perfusion state[80]	Any conduit ischaemia other than focal area without leak will require surgery.[80] High mortality rate
		Chylothorax	As for oesophagectomy

Severe and multiple injuries

Rebecca Schroll and Li C. Hsee

Trauma can be defined as physical injury from mechanical energy. It is usually categorised as blunt or penetrating. Around the world, trauma is the 6th leading cause of death, accounting for 10% of deaths worldwide and is the 4th leading cause of moderate to severe disability.[1] Severe blunt trauma is common, caused by road crashes, falls and, less frequently, blows and assaults. Severe penetrating trauma, usually from stabbings and gunshots, is less common except in larger cities of the United States, South Africa and areas of armed conflict.[1,2] Blunt injuries are frequently internal, multiple and not obvious initially. The severity of penetrating injury depends on its trajectory and the force of energy involved (see Chapter 107). The risk of missing serious injuries can only be lessened by a systematic approach and repeated assessments.[3–5]

Assessment and Priorities

Triage

An important first step is triage – sorting patients with acute life-threatening injuries and complications from those whose lives are not in danger. Depending on the complexity of injury, it is important to ensure resources are available for treatment. If institutional capacity is lacking, early consideration should be given towards transferring the patient to an advanced trauma unit. The severity of total body injury is related to the number of separate injuries present, and to the severity of individual injuries. Assessment can be made either at the scene of injury or on arrival at hospital. As in any emergency, assessment, diagnosis and treatment need to be concurrent. There is limited time for detailed histories, examinations, investigations or well-considered diagnoses before starting emergency care.

Recognition of Severity

Most patients with severe injury can be distinguished early by the following:

- *Signs of shock:* Shock is almost always hypovolaemic from blood loss, but other types of shock occasionally occur in trauma.
- *Depressed consciousness:* In the trauma patient, depressed consciousness can be related to brain injury, hypoxaemia, shock, alcohol or other ingested drugs, or precipitating neurological or cardiac events. Frequently, a combination of factors is present, and the precise extent of physical brain injury is not initially known. Initial treatment is, in any case, determined by the level of consciousness rather than its exact cause.
- *Breathing difficulty:* This is common in patients with trauma to the head, face, neck and chest. If rapid or distressed breathing is present then airway obstruction, laryngeal injury, pulmonary aspiration and lung or chest wall injury (especially pneumothorax and lung contusion) must be considered.

Priorities

A trauma patient often has multiple problems requiring attention. Determining priorities is not always easy. In general, the priorities are to:

- *support life:* the patient is kept alive with resuscitative techniques, whilst the various injuries and complications are attended to.
- *locate and control bleeding* , which may be varied.
- *prevent secondary brain injury, brainstem compression* and spinal cord damage.
- *diagnose and treat* all other injuries and complications.

Basic Treatment Principles

A systematic approach to managing severe and multiple trauma is important. Effective programmes developed by the American College of Surgeons are now well established.[6] A number of basic treatment principles apply to all severe trauma patients.

Emergency Assessment (Primary Survey)

Whilst airway, breathing and circulation (ABC) management is traditionally followed, battlefield trauma is managed using a <C>ABC approach, where <C> refers to the management of catastrophic external bleeding.[7] The treatment priorities are as follows:

- <C> – *Catastrophic bleeding:* Life-threatening external haemorrhage should be dealt with rapidly using field-dressing, tourniquet and/or topical haemostatic agents. Following management, or in the absence of catastrophic external bleeding, the ABC approach should be followed.
- *A – Airway obstruction:* It is suggested by noisy (or silent) breathing, with paradoxical chest movements and breathing distress, and inadequate airway protection from impaired gag reflexes in patients with depressed consciousness. Airway obstruction should be managed whilst maintaining cervical spine protection when appropriate.
- *B – Breathing difficulty:* It is suggested by tachypnoea, abnormal pattern of breathing, hypoxaemia, cyanosis or mental confusion.
- *C – Circulatory shock:* It is manifested initially by mental confusion, but as it progresses is manifested by cold peripheries with a delayed capillary refill, rapid weak pulse or low blood pressure.
- *D – Disability:* Neurological status should be evaluated by checking the pupils and score on the Glasgow Coma Scale (GCS). A decreased level of consciousness can be caused by poor cerebral perfusion, direct cerebral injuries, alcohol, recreational drugs and opiates.[6], [8]

- *E – Exposure:* The patient must be exposed for examination, but at the same time hypothermia must be prevented and dignity preserved. [6]

Oxygen and Ventilatory Therapy

Maximum oxygenation should be targeted to maintain adequate oxygen delivery to vital organs. High-flow oxygen by mask is given to all major trauma patients. Patients with severe trauma frequently require ventilatory support. A restless and uncooperative patient may require rapid sequence intubation to facilitate evaluation and resuscitation.

Blood Cross-Match and Tests

Blood is concurrently sent for baseline haematological and biochemical tests, including blood ethanol level. Blood ethanol level is clinically useful in assessing individual patients with depressed consciousness, quite apart from epidemiological and preventive medicine, [8] and for legal considerations. Blood should be cross-matched urgently, but it can be difficult to predict the amount of blood that will be required. Most institutions have policies on transfusion in unstable patients.

Fluid Resuscitation

Resuscitation fluids are given. Two large-bore (14- or 16-gauge) intravenous (IV) cannulae are inserted in the upper limb or external jugular veins. Alternatively, large-bore central venous access in the femoral veins (ideally under ultrasound guidance) or intraosseous cannulation can be useful initially if peripheral IV access is not obtainable.

Analgesia

Analgesia is easily overlooked. Opioid agents should be titrated IV, and not given intramuscularly or subcutaneously as the latter routes give unpredictable absorption in shock states. Large doses may be needed.

Urine Output

A urinary catheter is inserted unless a ruptured urethra is suspected (because of blood at the urinary meatus, severe fractured pelvis or abnormal prostate position on rectal examination), in which case a urethrogram is indicated before catheterisation. Urine output monitoring is an important guide to resuscitation.

Clinical Evaluation of Injuries (Secondary Survey)

Injuries are easily missed in an emergency, especially when one injury is obvious. A secondary survey should be performed once the primary survey and adjuncts are complete. [5], [6] The back and the front of the patient should be examined. Special attention is paid to regions with external lacerations, contusions and abrasions. All body regions are examined systematically.

Head

Neurological observations are made. The ears and nose are inspected for cerebrospinal fluid and blood, and the scalp is examined thoroughly.

Face

Bleeding into the airway should be excluded, and the face and jaws tested for abnormal mobility.

Spine

A cervical spine fracture or dislocation is assumed in all patients with depressed consciousness and appropriate mechanisms until proven otherwise. Signs of spinal cord injury should be sought (e.g. warm dilated peripheries from loss of vasomotor tone, diaphragmatic breathing, paralysis, priapism and loss of anal tone). The thoracic and lumbar spine should be inspected and palpated.

Thorax

Fractured ribs in themselves are not usually life threatening, but haemothorax, pneumothorax, lung contusion and chest wall instability (flail chest) will require attention if present. Tension pneumothorax is a life-threatening emergency that needs to be detected and treated early. Less common but very serious injuries can occur to the heart and great vessels.

Abdomen

The spleen, liver and mesenteries are often damaged. Retroperitoneal haemorrhage is common. Injuries to the pancreas, duodenum and other hollow viscera are less frequent and may be missed until signs of peritonitis occur. Renal injury with retroperitoneal haemorrhage is suggested by haematuria and loin pain.

Pelvis

Pelvic fractures may be difficult to detect clinically, especially in the unconscious patient. Blood loss may be massive, particularly with posterior fractures involving sacroiliac dislocation. Consideration of a pelvic binder may be useful in the initial stages of resuscitation. Ruptured bladder and ruptured urethra may occur with anterior fractures.

Extremities

A litre or more of blood may be lost into a fractured femur. Long-bone fractures are more serious when they are open, comminuted or displaced, or if associated with nerve or arterial damage.

External

Contusions may be extensive and serious, especially in falls from heights, and may be overlooked if the victim’s back is not examined. Road crash victims may sustain serious burns or abrasions.

Tertiary surveys, in which trauma patients undergo a repeat systematic examination approximately 48–72 hours after admission, further decrease the rate of missed injury. [5]

Shock in the Trauma Patient

The earliest, most constant and reliable signs of shock are seen in the peripheral circulation. A patient with cold, pale peripheries has shock until proven otherwise. Tachycardia is not always present and hypotension is a late sign of shock. The commonest form of shock by far in trauma is hypovolaemic shock due to haemorrhage.

Hypovolaemic Shock

If the neck veins are empty, hypovolaemic shock due to haemorrhage should be inferred. Possible sites of blood loss causing shock are:

- *external loss* , which is often obvious clinically from blood-soaked clothing and pooled blood, or from reports of significant blood loss at the scene.
- *major fractures* , which are clinically apparent due to deformity, swelling, crepitus, pain and tenderness (e.g. femurs) or seen on a plain X-ray (e.g. pelvis).
- *pleural cavity* , which can be detected on urgent chest X-ray or ultrasound. Intrapleural drains will reveal the amount and rate of blood loss.
- *peritoneal cavity* , which is most commonly detected initially by focused assessment with sonography for trauma (FAST), but depending on patient stability and clinical trajectory, may also be detected by computed tomography (CT) scan, laparotomy or, rarely, diagnostic peritoneal lavage (DPL). Clinical examination of the abdomen can be misleading when the patient is intoxicated, has depressed consciousness or has multiple injuries. A single clinical examination is of limited value; changes over time are more important.
- *retroperitoneum* , detected at laparotomy or by CT scan or inferred when all the above are negative, especially in the presence of

pelvic or lumbar spine fracture.

Other Causes of Shock

- *Cardiogenic Shock:* If the trauma patient with shock has distended neck veins, possible causes are tension pneumothorax, concurrent myocardial infarction, cardiac tamponade or myocardial contusion.
- *Neurological Shock:* Patients with paraplegia or tetraplegia from spinal cord injury may have low blood pressure with warm dilated peripheries accompanied by lax anal tone and by priapism in the male (see Chapter 81). This is a diagnosis of exclusion and all causes of hypovolaemic shock must be sought.
- *Septic Shock:* Occasionally, patients may develop septic shock due to pulmonary aspiration, missed hollow viscus injury or infection/necrotic wounds. This is unlikely to confuse the initial trauma assessment soon after injury but may require consideration some hours or a day or two later.

In addition to clinical exams, the following urgent imaging/diagnostic techniques may be utilised during the initial evaluation and treatment of severely injured trauma patients to determine the source of haemorrhagic shock and guide decision-making regarding urgent intervention.

Chest X-ray

Haemothorax as a cause of shock can be rapidly identified via chest X-ray in the trauma resuscitation bay. A supine film is usually sufficient in the major trauma setting. An erect film is better for showing intrapleural air or fluid, ruptured diaphragm, free abdominal gas and for defining an abnormal mediastinum, but it is often impractical in shock or suspected spinal injury. Tension pneumothorax is a clinical diagnosis; if suspected it should be treated immediately with insertion of an intercostal drain as attempting to confirm the diagnosis with chest X-ray may cause life-threatening delay.

Pelvis X-ray

Pelvic X-ray is an important adjunct of primary survey in a shocked trauma patient. Unexplained blood loss can be due to a missed pelvic fracture. A dislocated hip can also be missed in the setting of multiple injuries and is easily identifiable on plain film.

Ultrasound

The non-invasive nature and widespread availability of ultrasound in emergency departments have led FAST to become a standard method to detect haemoperitoneum in shocked trauma patients. It can also detect haemopericardium and pneumothorax.[9,10]

However, it is operator dependent and as such, should be performed by trained personnel. It has a high false negative rate of at least 22%–42%.[11–13] Therefore a negative result in a haemodynamically unstable patient who is suspected to have intra-abdominal haemorrhage should be interpreted with caution and additional diagnostic testing should be considered. Depending on clinical circumstances, options include CT scan (if patient stabilises), DPL, laparotomy or even repeat FAST after a short time interval.[11–13] Additionally, there is a small but important false positive rate for intra-abdominal bleeding. FAST is unable to diagnose some injuries for which laparotomy is eventually indicated, such as diaphragm or bowel rupture, or bleeding from pelvic fractures.[14] Its main usefulness is in the shocked patient, where a positive FAST indicates the need for immediate laparotomy without further investigation.[6,11,12]

Diagnostic Peritoneal Lavage

Whilst DPL was historically performed to rapidly diagnose intra-abdominal bleeding and bowel injury; it is now largely replaced by FAST and CT scan. However, it may still be used in unstable patients if FAST is unavailable or indeterminate. Drawbacks are that it is an invasive procedure, it may make subsequent clinical abdominal examination difficult, and caution is needed in pregnancy, previous abdominal surgery or massive pelvic injury.[6,14,15]

Computed Tomography Abdomen

Due to widespread availability, improved speed and accuracy, as well as its less invasive nature, CT scan has become the standard for diagnosis of torso injuries in patients who are sufficiently stable to tolerate it. Due to the time required to obtain a CT and the need to move the patient from the emergency department (ED) resuscitation area, it is ideal for stable patients or transient responders; it is less helpful for shocked and haemodynamically unstable patients. It should be performed quickly and safely, and interpreted by radiologists experienced in trauma. Most hospitals have a multiphasic trauma protocol for abdominal CT which utilises a single bolus of contrast to maximise injury detection.

Visualisation of solid abdominal and pelvic organs and haemorrhage is excellent. Diaphragm and hollow viscus injuries may be difficult to visualise on CT, but the presence of free fluid in the absence of solid organ injury raises suspicion of hollow viscus injury.[16, 17]

Whilst CT scans can improve outcomes for patients with high-risk mechanisms and clinical suspicion of torso injuries, indiscriminate CT scanning of all patients with major trauma (so-called ‘pan-scanning’) has not demonstrated improved outcomes. Possible benefits versus risks such as radiation exposure and contrast-induced kidney injury, and cost-effectiveness, must be considered.[18, 19]

Damage Control Resuscitation

Damage control surgery gained popularity in the 1990s as abbreviated surgery for patients in haemorrhagic shock. The priority is to stop bleeding and control contamination, followed by a period of resuscitation in ICU to arrest the lethal triad of acidosis, hypothermia and coagulopathy. This is followed by further surgery for definitive surgical management of injuries once the patient is more haemodynamically and metabolically stable.[20–22]

Following the evolution of the damage control surgery concept, advanced trauma resuscitation techniques became known ‘damage control resuscitation’ (DCR). This is a systematic approach to resuscitation for major exsanguinating trauma incorporating strategies of haemostatic resuscitation, permissive hypotension, minimal crystalloid use and early haemorrhage control through damage control surgery.[21–24]

Minimisation of Crystalloid

Almost all patients who are hypotensive or noticeably vasoconstricted will need a blood transfusion but, in general, early control of bleeding is the key. Isotonic saline or a balanced salt solution may be successfully used for patients with mild injuries and only a small volume deficit. However, if used for patients with haemorrhagic shock it is counterproductive, as large volumes cause haemodilution, coagulopathy, acidosis and oedema.[22] As little as 1.5 L crystalloid in trauma patients increases mortality, multiple organ failure, ARDS and abdominal compartment syndrome.[25,26] Albumin solutions increase mortality in patients with traumatic brain injury and are not recommended for resuscitation of trauma patients.[27]

Massive Transfusion Protocol

Shocked patients should be resuscitated early with blood and blood products, using rapid infusion devices. Type O Rh-negative ('universal donor') blood should be kept immediately available for rapid early transfusion, with the transition to type-specific blood administration as soon as possible. Fluid warmers should be used to prevent hypothermia, which can exacerbate coagulopathy and acidosis and cause arrhythmia.[28]

Coagulopathy is common in patients with haemorrhagic shock as clotting factors are consumed as well as lost; this can be made worse by unbalanced resuscitation. Hospitals that manage trauma patients should have a massive transfusion protocol (MTP), which should be activated early to provide haemostatic resuscitation for haemorrhaging patients. The goal of haemostatic resuscitation is early, balanced use of combined blood components as primary resuscitation fluids to achieve a 1:1:1 ratio of platelets, plasma and red blood cells.[29] If available, whole blood may be used instead of component therapy. Regular assessments of the efficacy of replacement therapy are required to guide and monitor coagulation parameters. Such MTP protocols are shown to improve survival.[22,24]

Thrombelastography (TEG) and thromboelastometry (ROTEM) are frequently used to guide real-time coagulation therapy.[22,30] Large-volume transfusion can cause hypocalcaemia, which should be monitored as part of an MTP. Haemostatic agents such as tranexamic acid (TXA) and other novel adjunct therapies are now available. Early TXA administration (<3 hours) has been shown to improve survival in haemorrhagic shock and is frequently incorporated into MTPs.[31, 32] However, the recently concluded PATCH trial showed that whilst prehospital TXA reduced early death due to haemorrhage in major trauma patients, there was no difference in the number of patients who survived with a favourable functional outcome at 6 months.[33] Further studies regarding long-term outcomes of TXA use in this patient population are needed. Prothrombin complex concentrate may be used in the setting of vitamin K antagonists.[31]

Permissive Hypotension

In penetrating trauma, there is some evidence that extensive fluid resuscitation prior to haemostasis may be detrimental, due to both higher blood pressure causing the displacement of blood clots and exacerbating ongoing haemorrhage, as well as dilution of coagulation factors and platelets.[34, 35]

Permissive hypotension is the limited use of crystalloids during the initial phase of resuscitation before definitive bleeding control. By allowing the blood pressure to be somewhat lower than usual whilst still high enough to maintain sufficient end-organ perfusion, secondary blood loss and haemodilution can be prevented. Whilst the optimal blood pressure is as yet unknown, the use of early hypotensive resuscitation with a target systolic blood pressure (SBP) of 90–100 mm Hg has demonstrated a survival benefit in haemorrhaging patients.[22, 23, 34–36]

Some enthusiasts have injudiciously extended DCR to other types of trauma.[37] However, great caution should be exercised before extending this concept to non-exsanguinating blunt trauma, particularly if a traumatic brain injury is present,[22, 38] or if the patient is remote from a trauma centre. Traumatic brain injury is often present in blunt trauma, which frequently involves several body regions. Hypotension is disastrous to an already injured brain, and must not be prolonged by under-resuscitation[38–40] (see Chapter 78).

The Exsanguinating Patient

With exsanguination secondary to penetrating thoracic injury, there is a place for emergency room thoracotomy, but this approach has little place in blunt trauma. [41] The exsanguinating blunt trauma patient requires rapid intubation, volume resuscitation, bilateral intrapleural decompression, chest and pelvic X-rays, FAST exam and a rapid trip to the operating room if it seems likely that the bleeding is in the thorax or abdomen.

In recent years, there has been high interest in resuscitative endovascular balloon occlusion of the aorta (REBOA) for shocked trauma patients, in which the aorta is temporarily occluded via transfemoral arterial catheterisation in the emergency department to improve proximal perfusion and limit abdominal/pelvic exsanguinating haemorrhage whilst en route to the operating theatre. However, results have been mixed. The recent UK-REBOA randomised controlled trial found that REBOA use did not reduce, and in fact, may increase mortality. [42]

Urine Output

Hourly urine output is a useful guide to resuscitation from shock. Minimal acceptable urine output is 0.5 mL/kg per hour, but 1–2 mL/kg per hour is more adequate. Furosemide has no place in initial resuscitation. Apart from adequate resuscitation, diuresis can be due to ethanol, mannitol, nephrogenic or neurogenic diabetes insipidus or non-oliguric renal failure. Polyuria may mask early recognition of acute renal failure.

Pulmonary Oedema

Pulmonary oedema during resuscitation may be related to fluid overload, direct lung trauma, aspiration of gastric contents, pulmonary responses to non-thoracic trauma (e.g. neurogenic pulmonary oedema) and reactions to resuscitation fluids. They can all cause leaky capillaries and produce non-cardiogenic pulmonary oedema.

Radiology for Trauma Patients

Patients with depressed consciousness, breathing difficulties or unstable circulation should be X-rayed in the emergency department, rather than sent to a radiology department remote from skilled resuscitation facilities. Conversely, extensive imaging examinations of shocked patients in the emergency department are unacceptable. Generally, extremity X-rays and other non-urgent adjunctive tests should be delayed until life-threatening injuries have been evaluated and either ruled out or treatment initiated. Initial imaging studies in shocked trauma patients are discussed above.

Plain Films

X-rays other than as discussed above should be performed after adequate resuscitation in the radiology department, operating room or ICU.

- *Extremity* X-rays: Extremity plain films to assess bony injuries are not urgent unless there is vascular injury. Therefore these films should not be taken urgently in the emergency department, unless the patient is going directly to the operating room for fracture fixation, and should not delay urgent evaluation of possible life-threatening injuries. If necessary, these films can be done in the operating room.
- *Abdominal X-rays* : These are of limited value in the initial evaluation of trauma, except for high-velocity penetrating injuries, such as gunshot wounds, in which X-ray can help determine trajectory and inform operative decision-making in patients who will proceed directly to the operating room.
- *Cervical, thoracic and lumbar spine X-rays:* These have been replaced by CT, which is more sensitive and specific. Spine X-rays are no longer a routine part of trauma evaluation.

CT Scans

CT scans assessing various body regions likely to be injured in major trauma patients are discussed individually later. However, the multiply injured major trauma patient often requires imaging of most/all of these regions, and many trauma centres now have protocols for ‘pan-CT scan’ for these patients to avoid missed injuries and unnecessary return trips for additional imaging. Institutional protocols for trauma CT scans ensure that the scans are completed in the correct sequence with appropriately timed intravenous contrast for the thoracic and abdominal/pelvic CT scans and any necessary neck or extremity CT angiography (CTA).

- *CT head* : This is vital in the evaluation and treatment of traumatic brain injuries.
- *CT cervical spine* : The most reliable way to exclude or delineate cervical spine injuries is by a c-spine CT scan, [43] which can conveniently be done when the patient is going to the CT scanner for other examinations. Further detail on the assessment of cervical spine injury can be found in Chapter 81 .
- *CT abdomen/* pelvis: This can be valuable to evaluate a patient who is haemodynamically sufficiently stable to tolerate the procedure safely.
- *CT thorax* : Whilst chest X-ray is typically sufficient to urgently identify and exclude immediately life-threatening injuries which require treatment in the emergency department such as pneumothorax or haemothorax, a thoracic CT scan can yield more information about the presence and nature of thoracic injuries including aortic and other great vessel injuries, mediastinal and pulmonary injuries and rib fractures. If aortic injury is suspected, a CT scan is the definitive diagnostic test. The use of aortic stent grafts for this injury, in locations where this technology is available, means that a CT scan not only is the best diagnostic test but also is necessary for preoperative planning. [45]
- *Neck CT angiography (CTA):* Should be used to screen for blunt cerebrovascular injury in patients with well-described associated injury patterns. [44] This can be conducted at the same time as other initial scans or on a return trip to the scanner but ideally should be conducted within 12 hours from injury.

Other Imaging

- *Urethrography* : This is used when urethral injury is suspected. Properly done CT abdomen may well demonstrate bladder injury;

otherwise, definitive CT *cystography* is commonly used.

- *Interventional radiology* : Percutaneous transcatheter angiography can be diagnostic as well as therapeutic when embolisation is utilised. It can provide life-saving haemostasis in massive retroperitoneal haemorrhage associated with pelvic fracture [46, 47] or hepatic laceration. [48, 49] This may be used in conjunction with operative fixation (for pelvic fractures) and/or packing (for pelvic fractures or liver injuries) either before or after embolisation. The logistics of managing such haemodynamically unstable patients in the radiology department are formidable. Embolisation can also be a useful adjunct to manage high-grade splenic and hepatic injuries in stable patients.

Traumatic Brain Injury (See Chapter 78)

Injuries to the head are common, but those requiring urgent cranial operations are less frequent. Traumatic brain injury (TBI) may initially be obvious amongst multiple injuries, but may not be the most important injury if there are more immediately life-threatening injuries. Conversely, minor TBI may seem initially unimportant; however, TBI is a major determinant of outcomes in critically injured patients and patients with suspected or confirmed TBI require careful management to optimise outcomes.

Initial Assessment and Treatment

Resuscitation measures, as in the emergency assessment (primary survey) section above, are undertaken. Suspected TBI severity is initially assessed using GCS, particularly motor score, pupil size and reactivity, as well as evaluation of lateralising signs.

Patients with one or both dilated unreactive pupils (indicative of transtentorial herniation) or a rapidly deteriorating level of consciousness not due to hypoxia or shock, may be given IV mannitol 0.25–1 g/kg body weight to control intracranial pressure and relieve brainstem compression until definitive diagnosis and treatment can be arranged. However, mannitol should be given only if the patient has been adequately volume-resuscitated as it causes osmotic diuresis and may exacerbate hypovolaemia. In the ICU, hypertonic saline may be preferred to mannitol because it is readily available and does not produce hypovolaemia; however, it may cause hypernatraemia and hyperchloraemia.[40] In patients who are receiving positive pressure ventilation, hyperventilation may be used as a temporising measure to reduce intracranial pressure (ICP). Target $PaCO_2$ should not be less than 25 mm Hg and should not be prolonged.[40]

Shocked trauma patients with or without traumatic brain injuries require the same fluid resuscitation. Treatment of shock and maintenance of cerebral perfusion is vital in the setting of TBI, as hypotension and hypoxaemia are detrimental to an already damaged brain.[38–40, 50] Increased severity and duration of both hypoxaemia and hypotension are associated with increased mortality and worse neurologic outcomes in TBI patients.[40] Whilst definitive guidelines for SBP targets in the multiply injured trauma patient are varied between minimum >90 and >110 mm Hg, there is general agreement that significant and/or prolonged arterial hypotension should be avoided.[38–40], [50] Patients who have suspected TBI should be given supplemental oxygen and monitored with continuous pulse oximetry. An adequate airway should be established and maintained via the most appropriate means available. Hypoxaemia (SpO_2 <90%) should be avoided.[49]

Factors such as hypoxaemia, shock, alcohol, analgesics, anaesthetic agents, muscle relaxants and other drugs can confound neurological signs. CT scans of the brain and cervical spine are indicated urgently in all patients with severe (GCS <8) or moderate (GCS 9–13) TBI. Patients with mild TBI (GCS 14–15) should undergo brain CT if they have any associated signs/symptoms such as rhinorrhea, haemotympanum, retroauricular haematoma, periorbital haematoma, obvious skull fractures, seizures or focal neurologic deficit, or if they have risk factors for intracranial haemorrhage such as coagulation disorder or take anticoagulant medication.[40] Patients with moderate TBI are at high risk for further deterioration and must be monitored very closely.

In an unstable patient, a laparotomy for intra-abdominal haemorrhage should take priority over a head CT scan, as haemorrhagic shock is more urgently life-threatening.[40], [51]

Severity and Morbidity of Trauma

Severity of injury is measured by the abbreviated injury scale (AIS), updated over the years, most recently in 2015.[52–54] AIS divides the body into six regions: Head and neck, face, thorax, abdomen, pelvis and extremities and external. Specific injuries in each body region are coded on a scale of 1 (minor), 2 (moderate), 3 (serious, not life threatening), 4 (severe, life threatening, survival probable), 5 (critical, survival uncertain) and 6 (unrevivable). The AIS was designed for motor vehicle injuries but has been validated for blunt and penetrating trauma. It can provide a basis for research, education, audit and allocation of resources.

Severity of trauma is related not just to the severity of individual injuries but also to the combined effects of multiple injuries. Multiple injuries are graded by the injury severity score (ISS), which is an empirical system based on the AIS grades for the three worst body regions.[55,56] ISS gives a score between 0 and 75 for total body injury; 16 or more indicates major trauma. Death with an ISS below 24 should be rare. Above an ISS of 25, there is a stepwise increase in mortality, with very high rates over 50.[57,58]

The AIS and ISS study mostly the anatomy of injury. Other factors influence trauma mortality and morbidity, including age, pre-existing health, degree of physiological derangement, standard of prehospital and early hospital care and complications. Degree of physiological derangement can be measured by the revised trauma score (RTS),[59] which is computed from the coded values of the GCS, systolic blood pressure and respiratory rate, usually at admission to the emergency department. The trauma and injury severity score (TRISS) is based on the RTS, ISS and patient age.[60] It correlates well with outcome and has been used to compile survival norms for blunt and penetrating trauma.[57,58] Physiological scoring systems such as Acute Physiology and Chronic Health Evaluation (APACHE) do not work well for trauma patients.[61,62] Preinjury illness (co-morbidity) has a profound effect on trauma outcome.[63]

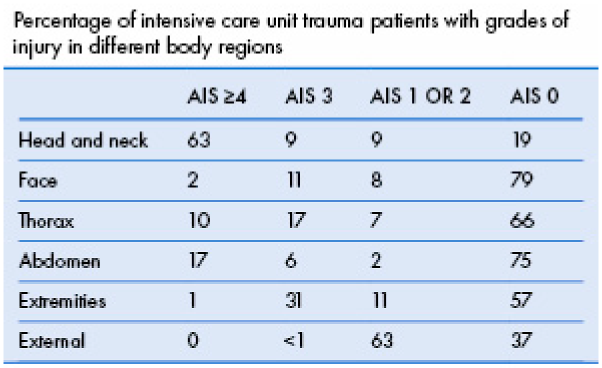
Shock influences trauma mortality and morbidity. Complications of shock include renal failure, ARDS, sepsis, liver failure and multiorgan dysfunction.[64,65]

Epidemiology of Injuries

Only a minority of victims of the most severe trauma reach hospital alive.[65,66] The majority of deaths are immediate (within minutes) at the scene of injury. Some deaths are early (within hours) in the emergency department or the operating room, and a few are late (after days or weeks) and occur in the ICU or ward.[67] Those in the ICU are mostly from severe head injury within a few days and, less commonly, multiorgan dysfunction later.

Of trauma admissions to hospitals, only a minority have severe or multiple trauma.[68] In order of frequency, life-threatening injuries involve the head, abdomen and chest (Table 77.1), and are often multiple. The hospital services that this small number of severely injured patients use out of proportion to their numbers are major surgery, intensive care, radiography and CT scanning. [68] Major trauma outcome studies in the United States, [57] the United Kingdom [58] and Australasia [69], [70] offer valuable epidemiological data. The US study found that the mortality of direct admissions is strongly related to serious head injury.

Table 77.1



Percentage of intensive care unit trauma patients with grades of injury in different body regions

	AIS ≥4	AIS 3	AIS 1 OR 2	AIS 0
Head and neck	63	9	9	19
Face	2	11	8	79
Thorax	10	17	7	66
Abdomen	17	6	2	75
Extremities	1	31	11	57
External	0	<1	63	37

Data on 5031 trauma patients (excluding burns) in the Department of Critical Care Medicine, Auckland City Hospital, 1988–2011. AIS-80 codes: 0 = no injury; 1 = minor; 2 = moderate; 3 = serious, not life threatening; 4 = severe, life threatening, survival probable; 5 = critical, survival uncertain; 6 = unsurvivable. In tertiary referral centres (like Auckland City Hospital) these figures will vary with the mix of local and referred patients. [62]

AIS , Abbreviated injury scale.

Organisation of Trauma Care

Many of the problems of trauma care are organisational. Problems faced by health authorities are the provision of advanced care at the scene of injury, rapid transportation to hospitals, policies on which hospitals should receive trauma patients, systems for rapid evaluation and decision-making in hospitals and rapid, safe patient transfer between hospitals. If survival from major trauma is to be maximised then prehospital and hospital care must be coordinated.

Regionalisation of trauma care has become an accepted concept.[2,71] Trauma centres are designated hospitals that meet certain requirements. The main prerequisites are rapidly available experienced general/trauma surgeons, anaesthetists and neurosurgeons and a minimum number of patients seen annually for staff expertise. Regionalisation involves the concept of ambulances bypassing non-designated hospitals.[2] Helicopters are often used to speed patient transportation.[72] Trauma teams are teams of surgeons and intensivists or anaesthetists who immediately attend to the trauma victim on arrival at hospital.[2–4]

Trauma registries and databases are important tools in organising and improving trauma care. The UK major trauma outcome study[56] showed that the doctors in charge of resuscitation were often junior, delays in performing urgent operations were common and the number of preventable deaths was significant. A hospital may not see enough trauma patients to justify a trauma team or supply adequate experience for its staff, and may not have all the facilities required by trauma patients. Transfer to a trauma hospital may be desirable, but geography and limited transport facilities may make such transfers hazardous.

In Western countries, trauma is a leading cause of death and disability under the age of 38 years.[1,6,57] Reduction of mortality and morbidity depends on public education, new legislations, on-site advanced care, rapid evacuation, hospital trauma expertise and coordination of services.[73,74]

Severe head injuries

Mark Howard Wilson

Introduction

Traumatic brain injury (TBI) affects more than 50 million people worldwide each year. [1] Trauma is the commonest cause of death in under 45 year olds with brain injury comprising the majority of these. The morbidity associated with TBI is considerable, having effects not just on the individual, but their loved ones and society. The prevalence of TBI in the homeless population is 53% [2] and 65% in the prison population [3] demonstrating it is a disease of the vulnerable and goes on to make people vulnerable. Intensive care plays a central role in the management of severe brain injury and our aim is to try to ensure the patient remains as close to their pre-morbid 'self' as possible. There are multiple physiological parameters that can be measured and optimised to minimise the evolvement of secondary brain injury. This chapter outlines these concepts and management principles.

Primary and Secondary Brain Injury

Whilst definitions vary, primary brain injury is usually considered as the injury that occurs at the moment of impact. Minimising primary injury is the domain of public health and policy makers to reduce injury occurrence and severity through, for example, improved road design and enforcing the wearing of helmets and seat belts. Secondary brain injury is the injury that evolves after the moment of impact. There are many potential secondary brain injuries but hypoxia, hypotension, expanding haematoma/rise in intracranial pressure (ICP) and seizures are common. Secondary injuries compound morbidity and worsen neurological outcomes. The majority of ICU care relates to preventing or reducing these injuries. [4]

The commonest mechanisms of brain injury vary around the world, but road traffic collisions are still the commonest globally. In Western countries, falls, especially amongst the elderly are increasing rapidly. [5] Assaults make up a large third category. Whilst these are the common mechanisms, they are not the causes. Spending time in a neurotrauma unit, it quickly becomes apparent that alcohol, drugs, mental health and underlying poverty are associated with many of these injuries. As clinicians, we have a role in trying to break the cycle of brain injury, social decline and further head injury that seems to be a spiral so many patients, who do not have family or social support, enter.

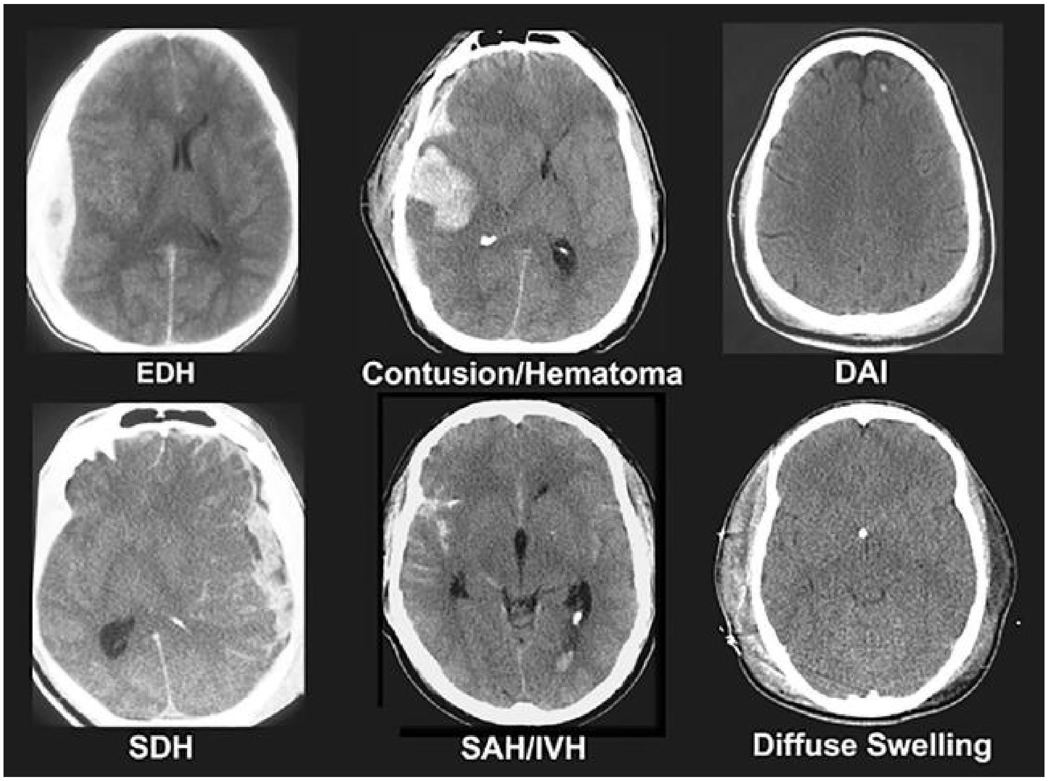
In most parts of the world blunt injury is by far the commonest, but in war-torn areas and in some areas of the United States, penetrating injuries from firearms or shrapnel are sadly common. This chapter will focus on blunt injury, though the principles of management are the same. [6] The important surgical differences for penetrating injuries are debridement/decontamination and concurrent vascular injury that may require interventional radiology.

Types of Blunt Brain Injury

Most hospitals have a ‘traumatic brain injury protocol’, placing all types of brain injury under one ‘umbrella’. This is a legacy of the pre-computed tomography (CT) scan days, but it is vital that we personalise this very basic element of medicine to at least treat the disease process we see. Do all forms of TBI really benefit from the same cerebral perfusion pressure? Fig. 78.1 shows the common forms of ‘brain injury’, but consider carefully whether the brain is actually injured. Also, remember that many of these injuries can occur concurrently. It should also be noted that most of these injuries are shearing injuries caused by sudden deceleration of the head (e.g. hitting a windscreen) whilst the brain continues to move. The exception is extradural haematoma which is usually caused by a blow to the stationary head causing a skull fracture.

- **Extradural haematoma** – Caused by a blow to the head, fracturing the skull and usually rupturing a branch of the middle meningeal artery. This arterial bleed strips the dura away from the inside of the skull. Being bound at the suture margins, the blood forms a ‘lens’ shape. This is not a brain injury. If operated on rapidly, these patients go home completely well. If left, the brain shift can cause underlying brain ischaemia and induce a brain injury.
- **Subdural haematoma** – This is a deceleration/rotation injury caused by the head moving and suddenly stopping (e.g. hitting the floor) whilst the brain continues, stressing and rupturing the venous connections between the surface of the brain and the sagittal sinus. This bleed then accumulates across the surface of the brain under the dura. This is also not a brain injury. Evacuating chronic subdural haematoma can return a patient completely to their normal state. Acute subdural haematomas are, however, commonly associated with brain injury as they have a significant deceleration component that may have resulted in an element of diffuse axonal injury, contusion or subarachnoid bleeding.
- **Contusion/haematoma** – This is an actual parenchymal brain injury, usually caused by sudden deceleration. They often occur in the frontal and temporal lobes where the brain interacts with the rough surface of the anterior fossa floor. Like any bruise, they tend to evolve and worsen, especially in those who are anticoagulated. The resulting neurological injury often correlates to the location of the contusion.
- **Traumatic subarachnoid haemorrhage** – This usually relates to a shearing injury that disrupts the small vessels overlying the surface of the brain.
- **Diffuse axonal injury** – This is a rotational, usually sudden deceleration injury, resulting in disruption at the grey-white interfaces and associated microvessels. It results in axonal disruption and microhaemorrhages visible on susceptibility-weighted MRI.
- **Hypoxic brain injury** – This may occur either secondary to loss of airways which is common with reduced consciousness, or because

of impact brain apnoea. [7]



The composite visual of six C T brain scans arranged in two rows shows axial views of the brain. Each panel is labelled to show different types of brain injuries. The top row from left to right shows E D H with a biconvex hyperdense area along the skull margin, contusion or hematoma with multiple mixed density areas, and D A I with a normal appearing scan labelled accordingly. The bottom row from left to right shows S D H with a crescent-shaped hyperdensity along the cortical margin, S A H and I V H with hyperdensities in the subarachnoid space and ventricles, and diffuse swelling with compressed sulci and reduced ventricular visibility. Each scan highlights a different traumatic brain injury pattern.

FIG. 78.1 Types of brain injury. (From Saatman KE, Duhaime A-C, Bullock R, et al. Classification of traumatic brain injury for targeted

therapies. *J Neurotraum* . 2008;25:719–38.)

Physiological Variables in TBI Management

The core principles of TBI management are to maintain neuronal oxygenation through adequate cerebral perfusion with well-oxygenated blood. This requires the minimisation of hypoxia and the maintenance of blood pressure. An episode of hypoxia or hypotension is associated with a doubling of mortality in TBI. [4]

Cerebral Perfusion Pressure

Cerebral perfusion pressure is equal to the mean arterial pressure minus the intracranial pressure ($CPP = MAP - ICP$). This seminal equation is used to guide the maintenance/support of blood pressure in TBI patients. It has been thought that cerebral autoregulation is often lost in severe TBI and a higher CPP is necessary to maintain adequate cerebral blood flow.

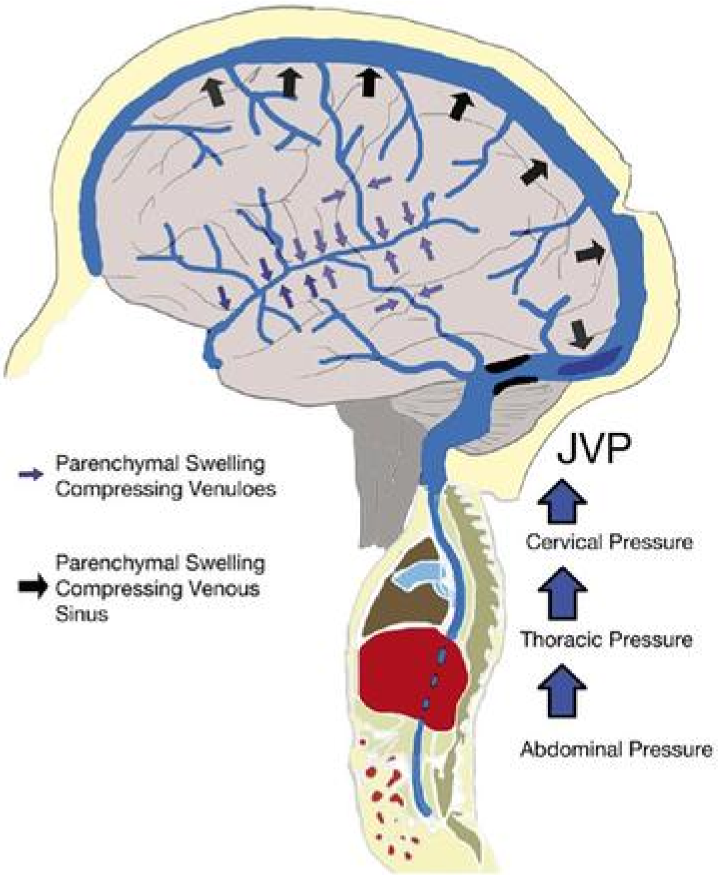
The evidence for a specific target CPP for all TBI, however, is lacking. [8] The techniques to raise CPP (administration of fluids or inotropes) also carry risks. Current Brain Trauma Foundation guidelines are to maintain a CPP between 50 and 70 mm Hg. Multimodal monitoring and specific targeting of physiological parameters (e.g. using indices such as cerebrovascular autoregulatory reserve) may be better than trying to target a one-size-fits-all CPP.

It should be noted that most patients with a TBI are managed head up at 30 degrees. Therefore measuring MAP with reference to the right atrium is wrong. Both ICP and MAP should be referenced (zeroed) to the level of the brain (tragus) (the difference between the right atrium and the head can be 11 mm Hg at 30 degrees head-up tilt).

Intracranial Pressure

The Monroe-Kellie doctrine forms the basis of our understanding of ICP. In summary, the skull can be considered a closed box and if there is an expanding mass within it (e.g. a haematoma), CSF and venous blood can be displaced to grant a period of ‘compliance’ and no pressure rise. However, once that limit is exhausted, pressure rises exponentially. At this point, the brain has to herniate, either down the foramen magnum (coning) or under the falx (transtentorial herniation).

This is a somewhat static model of ICP that does not take into account cerebral blood flow. In the acute scenario, an increase in the volume of arterial blood entering the cranium, or any restriction or obstruction to venous outflow has a rapid and significant effect on ICP.[9] This is witnessed with pressure over the jugular veins of a patient with an ICP monitor in. However, there are many haemodynamic factors that influence ICP. Acute hypoxaemia (e.g. from a chest infection) increases cerebral blood flow. The limited jugular venous outflow means that this results in an ICP rise. Intracranially, venous sinus injury can also restrict outflow. Tight collars putting pressure on the neck, positive pressure ventilation, and increased abdominal pressures (e.g. from constipation or from transporting a patient with an oxygen cylinder resting on them) all increase venous and therefore intracranial pressures. Fig. 78.2 demonstrates the more holistic view of ICP beyond it being just an intracranial phenomenon.



Parenchymal Swelling Compressing Venuloes
Parenchymal Swelling Compressing Venous Sinus
JVP
Cervical Pressure
Thoracic Pressure
Abdominal Pressure

The sagittal diagram of the head and upper body illustrates venous drainage pathways and the effect of parenchymal swelling. The brain is shown with branching venous channels. Thin arrows show parenchymal swelling compressing venules, while thick arrows show parenchymal swelling compressing venous sinuses. The jugular venous pathway is labelled J V P and extends downward through the neck and thorax to the abdomen. Large upward-pointing arrows are labelled cervical pressure, thoracic pressure, and abdominal pressure. These labels denote the pressure influences on jugular venous return along the vertical axis. The spinal cord, brainstem, and some thoracoabdominal structures are also illustrated.

FIG. 78.2 Diagram demonstrating that relative venous outflow restriction can occur intracranially (with compression/obstruction (e.g. with thrombus or fractures) of isolated or diffuse structures) and extracranially (from cervical, thoracic and abdominal pressures). (From Wilson MH. Monro-Kellie 2.0: The dynamic vascular and venous pathophysiological components of intracranial pressure. *J Cereb Blood Flow Metabolism* . 2016;36:1338–50.)

Measurement of ICP

There are non- and minimally invasive methods to estimate ICP. These include optic nerve sheath diameter (normal is <6 mm), fundoscopy to look for papiloedema, palpation of an open fontanelle in a neonate and lumbar puncture. None of these are truly reliable methods to continuously monitor the trends and changes in ICP following trauma.

The gold standard method of measuring ICP is through an external ventricular drain (EVD) placed into the ventricular system (at the level of the foramen of Monro). An advantage of an EVD is that it can also be used to remove CSF and hence lower ICP. The disadvantages are that placement usually requires to be done in an operating theatre and the increased risk of ventriculitis. More common is an intraparencymal monitor or ‘bolt’. These usually use a small pressure transducer, or pressure-sensitive diaphragm on a fibre optic cable and are placed within the frontal parenchyma via a twist drill to penetrate the skull. [10] They are easier to place but sometimes have issues with drift requiring re-zeroing.

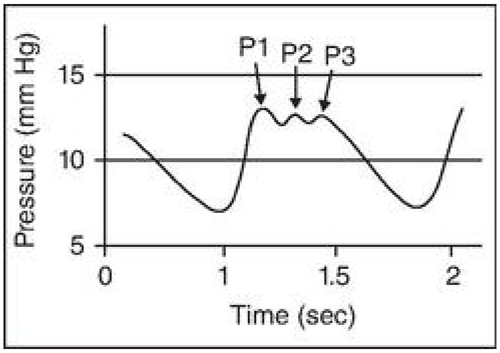
It should be remembered that high ICP following trauma is associated with a poor outcome. This is to be expected, but it may be the severity of brain injury that results in a high ICP, rather than the management of it that reduces mortality. It has been demonstrated that ICP monitoring is no better than serial CT scanning; [11] however, CT scanning itself does give an indication of ICP.

ICP Waves

In the horizontal position, a normal ICP is between 7 and 15 mm Hg. In a vertical position, it may be as low as −10 mm Hg. In TBI anything above 20 mm Hg is abnormal and above 25 mm Hg, aggressive treatment is required.

An ICP pressure wave classically has 3 peaks in a cardiac cycle (Fig. 78.3).

If the P2 peak rises above P1, it implies there is intracranial hypertension. As these waves accumulate over time, they can rise to a crescendo called Lundberg A waves implying imminent herniation or be chaotic in nature, Lundberg B waves imply unstable ICP.



The graph with pressure in millimetres of mercury plotted on the vertical axis, ranging from 5 to 15 and time in seconds on the horizontal axis, ranging from 0 to 2. The line shows a wave-like pressure pattern with three closely spaced upward deflections occurring between 1 and 1.5 seconds. These peaks are labelled P 1, P 2, and P 3 with downward-pointing arrows. The curve begins at a moderate pressure level, dips slightly, then rises toward the first peak at P 1, followed by two smaller peaks P 2 and P 3 before falling again. The labelling presents three distinct pressure components within a single cycle.

FIG. 78.3 Three peaks in a cardiac cycle. P1 = percussion wave (arterial pulsation); P2 = tidal wave (intracranial compliance); P3 = dicrotic wave (venous pulsation).

Intracranial Pressure Derived Cerebrovascular Reactivity Indices

Cerebrovascular pressure reactivity index (PRx) incorporates the philosophy of assessing cerebrovascular reactions by observing the response of ICP to slow spontaneous changes in arterial blood pressure (ABP). [12] When the cerebrovascular bed reacts normally, any change in ABP results in an inverse change in cerebral blood volume and ICP. If the reactivity is not normal, the ABP changes are transmitted to ICP. The correlation coefficient of ICP and ABP over 40 cycles provides the PRx. A positive value means ICP follows a rise in ABP (a non-reactive vascular bed), whilst negative PRx implies a working autoregulation. [13]

Brain Oxygenation

Brain ischaemia is thought to be a significant secondary brain injury and measuring and minimising it should be of benefit. There are a number of tools that can be used to measure or infer brain oxygenation. Near-infrared spectroscopy (NIRS) is a non-invasive tool that has not extended significantly beyond being a research technique. Invasive partial pressure of brain tissue oxygen ($PbtO_2$) is another tool that can give localised brain oxygenation measurements. This has been the subject of many trials as is more widely used, however, significant consideration has to be given to the resulting measurement. The probe reflects the brain oxygenation where it is (is it in an already infarcted brain, is it on a haematoma or in the penumbra zone?). Reactionary treatments (e.g. increasing inspired oxygen partial pressure) can have negative impacts (e.g. atelectasis and lung injury) and hence this tool needs to be used with caution. The BOOST 2 study of 119 patients demonstrated invasive brain oxygenation monitoring was safe and resulted in reduced hypoxic time, however, it was not powered for clinical outcomes. [14] A number of studies are investigating this further. A recent meta-analysis has shown that use is associated with increased survival and reduced ICP. [15]

Microdialysis

Microdialysis, in particular, the measurement of lactate:pyruvate ratios is another tool that can increase our knowledge of the metabolic state of the underlying brain, however, this has remained largely within the research sphere. [16] The ability to measure glucose and biomarkers may increase its use, however, to date, there is no demonstrable benefit in the outcome.

Management of ICP

Methods to lower ICP are listed in Box 78.1 . The Brain Trauma Foundation uses a ‘tiered’ approach. In short, starting with simple things such as position, optimising sedation/paralysis and ventilation, then adding in osmotic diuretics before surgical or more radical (e.g. barbiturate) medical treatments should occur. A few treatments in particular warrant specific discussion.

Box 78.1

Techniques to lower ICP

- Loosen collar – improve venous drainage
- Position (30-degree head up)
- Adequate sedation/analagesia
- Paralysis
- Avoid any additional pressure on chest/abdomen
- Normalise $EtCO_2$ if intubated (4.5 kPa) (avoid excessive positive pressure)
- Osmotic diuretics
- EVD insertion
- Decompressive craniectomy/thiopentone.

Osmotic Diuretics

Osmotic diuretics improve cerebral perfusion by rapidly improving the rheology of the blood. This occurs by the extraction of extracellular fluid from soft tissues haemodiluting the blood. They then have their osmotic effect on the brain parenchyma itself. Two commonly used osmotic diuretics are mannitol (0.25–2 g/kg) and hypertonic saline (3% 3–5 mL/kg). There is no clear benefit of one over the other, however, mannitol can precipitate out in the cold (so hypertonic saline is preferred in the pre-hospital environment) and may have a higher incidence of renal complications. Hypertonic saline is probably better at maintaining blood pressure in the polytrauma patient.

Cooling

Cooling (after adequate pharmacological paralysis) was once considered a mainstay of neuro-ICU management based on the theory that it reduces cerebral metabolism would reduce brain injury evolvement. A large study (Eurotherm) in which patients were cooled to 32–35°C was stopped early due to excess mortality. [17] Similarly, a largely pre-hospital study that used infusion of cold saline to induce hypothermia also showed no evidence of benefit. [18]

Antiseizure Prophylaxis

The use of antiseizure medication varies considerably across institutions. The concern is that for a patient, especially on the edge of cerebral compliance, a seizure could result in brain herniation. Prolonged subclinical seizures might also have a negative effect through the increased metabolism associated. As such, most institutions will administer phenytoin or levetiracetam for one week. Whilst this reduces the incidence of early seizure it does not appear to influence long-term seizure risk.

Ventilation of TBI Patients

The mode of ventilation of TBI patients is often debated with a belief that high positive end-expiratory pressures (PEEP) raise ICP. Whilst this may be the case, protective strategies to improve oxygenation should be safely considered and low tidal volume/high PEEP is not associated with increased mortality. [19] The previously common practice of hyperventilation to lower ICP has been shown to increase brain ischaemia. [20] As such, most guidelines now state to maintain a normal $PaCO_2$ of ∼4.8 kPa. Temporary hyperventilation can still be used when a herniation is impending (e.g. a blown pupil) to buy a few extra minutes to enable intervention.

Surgical Management

Surgical interventions are often instigated when medical treatment of raised ICP has been exhausted.

External Ventricular Drain/Lumbar Drain

The insertion of an external ventricular drain (EVD) enables CSF removal as well as pressure measurement. These drains normally require placement in an operating theatre, though there are newer types that can be placed through a twist drill in an ICU. Traditionally, lumbar drains were thought to increase the risk of coning; however, they are becoming more commonly used in some units for refractory intracranial hypertension as this previously feared complication does not appear to occur. [21]

Both EVDs and lumbar drains normally drain into a CSF measuring system such as a Becker drain. It is vital that this is set up correctly (zeroed at the level of the foramen of Monroe) for accurate measurements. It should be noted that there is filter paper in the chamber. If this gets wet (e.g. by laying the drain on the patient during transport), the system will stop working.

Craniotomy for Extra-Axial Haematoma

Extradural haematoma and subdural haematoma are not ‘brain injuries’ themselves, but the brain shift they cause and in the case of subdural haematoma, the shearing (and hence parenchymal injury) they are associated with can have devastating effects. As such, when these are of significant volume, having significant mass effects or raising ICP, they should be evacuated and the more rapidly this is done, the better the neurological outcome. Whilst burr holes may be effective for chronic (and therefore liquid) subdural haematoma, usually a craniotomy (where the bone is removed, the blood evacuated and then the bone replaced) is required. In the case of extradural haematoma, underlying brain injury (and therefore swelling is rare), and hence the bone is put back at the end of the operation (a craniotomy). In circumstances where the brain is very injured and expected to swell, the bone can be left out (a craniectomy) with the knowledge that they might well require an elective cranioplasty at a later stage if they survive. A recent study has demonstrated, that when in equipoise, and patients were randomised to craniectomy or craniotomy, there was no difference in mortality but those who had craniotomy often (14.6% vs. 6.9%) required further surgery and those that had craniectomy, had more wound complications (12.2% vs. 3.9%). [22]

Craniotomy for Intraparenchymal Haematoma

The role of surgery in traumatic intraparenchymal haematoma is less clear [23] as are the different techniques (decompression vs. aspiration), however, with raised ICP or significant mass effect, if not futile, this is a surgical option.

Decompressive Craniectomy

The removal of a large piece of skull enables the brain to expand, thereby reducing ICP and improving both brain perfusion and venous drainage. However, the timing of this end-stage treatment for refractory intracranial hypertension is important. The decompressive craniectomy (DECRA) in Diffuse TBI study randomised patients to standard care (including barbiturates) or DECRA if ICP was >20 mm Hg for 15 minutes. [24] This study demonstrated more unfavourable neurological outcomes in those undergoing surgery. But many would argue the threshold was too low. The Rescue ICP study randomised patients when ICP was >25 mm Hg for 1 to 12 hours. [25] This demonstrated 22 more survivors per 100 treated in the surgical arm, however, many had a very poor quality of life, bringing into question the ethics of this procedure and how best to decide which patients will benefit. In a longer time analysis, those who had decompression had a sustained reduction in mortality at 24 months and were more likely to improve compared to those who received medical care. [26]

Minimising Bleeding

Brain injury can itself induce coagulopathy.[27] The use of viscoelastic haemostatic assays such as thromboelastography can guide the management of this in terms of blood product administration. There is some evidence that resuscitating patients in the early phase with plasma improves survival.[28]

There are also many patients (especially in the falling elderly population) who take antiplatelets or anticoagulants to minimise the risk of stroke or cardiac ischaemia. The management of these is considered below.

Tranexamic Acid

Tranexamic acid (TXA) is an antifibrinolytic preventing plasminogen conversion to plasmin thereby preventing fibrin degradation. CRASH-3, a large multinational study has demonstrated that TXA reduces brain injury-related mortality in mild to moderately severe TBI (relative risk 0.78)[29] with earlier treatment being more effective. Other studies have not demonstrated benefits at least in the moderate to severe category.[30] As such, there is some controversy, but given previous studies had demonstrated benefits in polytrauma, TXA is now part of many guidelines, recommending it is given as soon as possible after, or at least within an hour of injury.

Patients on Antiplatelet Therapy

There is a temptation to manage patients who are on antiplatelet medications (e.g. aspirin and clopidogrel) who have, for example a parenchymal contusion, with platelets to attempt to minimise evolvement. There is no good evidence to support this. In those with spontaneous intracerebral haematoma (ICH), administration of platelets has been associated with a worse outcome[31] and smaller studies have had similar results for traumatic ICH. If, however, a patient is planned for surgery, it is standard practice to aim for a platelet count of $>100 \times 10^{9}$/L to cover the surgical procedure.

Patients on Warfarin

Warfarin is a vitamin K antagonist and hence reduces the function of clotting factors II, VII, IX and X. An international normalised ratio (INR) test can determine if the patient’s prothrombin time is increased and if necessary, prothrombin concentrate can be given (in addition to vitamin K) to reverse this rapidly.

Patients on Direct Oral Anticoagulants (DOACS)

These newer anticoagulants do not need the regular monitoring that warfarin does. They are, however, more difficult to reverse with such agents being more expensive and difficult to obtain (e.g. dabigataran is reversed by idarucizumab; rivaroxaban is reversed by andexanate alfa). As such, most hospitals will still use prothrombin complex or fresh frozen plasma as reversal in these patients.

Deep Vein Thrombosis Prophylaxis

Minimising the risk of deep vein thrombosis (DVT) and its complications is important in TBI patients who often have prolonged immobility. But often there are concerns that anticoagulation may cause enlargement of intracranial haematoma or contusions. As such maximising mechanical tools (e.g. with pneumatic compression stockings) should be undertaken and if prolonged or especially high risk, consideration should be given to the insertion of an inferior vena cava filter. There are no universal guidelines but prophylaxis with low molecular weight heparin should be considered on a per-patient basis. In most cases it is safe at 24 hours and good evidence of safety by 72 hours. [32]

Pharmacological Management of TBI

Critical care management of TBI comprises the use of many standard sedatives (midazolam/propofol) and when required, paralytic agents.

Caution should be taken with longer-term use of propofol (especially in younger patients) at risk of propofol infusion syndrome.

There have been many proposed 'neuroprotective' agents which have shown benefit in animal models, but as yet, have not shown benefit in humans. This is largely because often they are given much later clinically compared to animal studies and the mechanisms of injury are more heterogeneous. Examples include the use of erythropoietin in TBI which has not shown any improvement in neurological outcomes at 6 months [33] and progesterone, which again showed no benefit even with early administration. [34]

Fluid Management in TBI

Optimal fluid management in TBI is important to reduce brain oedema, minimise venous hypertension whilst also adequately supporting cerebral perfusion. The administration of albumin in TBI is associated with higher mortality than using saline [35] and although not specifically related to brain injury, there is no evidence that balanced solutions offer any advantage over normal saline. [36]

Devastating Brain Injury

Severe TBI can sometimes (or indeed quite often) be unsurvivable. It can also be survivable but with 'devastating' neurological results. It is often difficult to predict neurological outcomes based on the conscious level and first CT scan that is seen at the time of injury and extreme caution should be used when labelling an injury as 'devastating' or 'unsurvivable'. There are, however, times when prolonging resuscitation efforts is clearly futile. The pathway for people who had such an injury was traditionally to either be extubated in the emergency department or taken to a side room and kept comfortable. There are several reasons why new guidance has been given around this. [37] Firstly, some people who are thought to have terrible brain injuries, survive; it is difficult to know all the facts immediately. [38] The rapidity of decisions is also not good for families, nor does it give time for consideration of organ donation. As such, where resources allow, admission to a higher dependency environment for support whilst all facts are established and to allow time for the family is at the core of the current guidance.

Long-Term Considerations

Navigating the path of management for severe TBI patients is different for every patient. An understanding from the next of kin can help form a view of what the patients themselves would have wanted in such circumstances. Many relatives will say that their loved one would not have wanted to have lived being so dependent on others. Many other relatives wish for life to be preserved at all costs. Navigating this path has to be done with realistic prognostication. This comes from a combination of neurological examination to assess recovery, consideration of the imaging and any relevant neurophysiology (e.g. electroencephalogram (EEG) results). Time is another useful domain. It enables all to see any rate of recovery and also helps families to come to terms with the situation. Often during this time, the discussion of a tracheostomy occurs. The timing of tracheostomy is often controversial (with some evidence of reduced length of stay in ICU, but delayed entry to rehabilitation). It also marks a more prolonged period of supportive care. The involvement of a complete team of therapists, neurologists, nurses and rehabilitation specialists is important in making these prognostication decisions.

Summary

Severe brain injury is common and there are many variables that can be monitored and supported within an intensive care environment. Whilst there are often protocols for TBI management, the actual underlying pathology and the situation of the individual patient must always be considered. The guiding principles of maintaining good cerebral oxygenation with lower intracranial pressures whilst recovery occurs are at the core of good management. The minimisation of secondary injury, the preservation of neurons and keeping the patient as close to the person they were before the injury is the aim of good neurointensive care.

Maxillofacial and upper-airway injuries

Jason Pincus, Alexander M. Bobinskas and Scott Charles Borgna

Maxillofacial Injuries

Blunt or penetrating maxillofacial injuries may be isolated or part of multisystem trauma. Life-threatening associated injuries occur in 6.2% of patients with facial injuries and commonly include head, cervical spine and chest injuries. [1] Life-threatening airway haemorrhage and airway obstruction are challenging issues and require skilled airway management to prevent adverse outcomes. This chapter outlines the basic anatomy, pathology, complications and common pitfalls in the emergency management of maxillofacial and upper-airway trauma.

Epidemiology

Maxillofacial trauma occurs most frequently in the 15- to 25-year age group and occurs three to five times more often in males than in females. [1–3] Blunt injury mechanisms account for nearly 98% of all maxillofacial injuries. [4] Falls, interpersonal violence and motor vehicle accidents account for the majority of injuries, with sporting injuries and industrial accidents being other common causes. [2, 3] Preceding use of alcohol is widely variable and particularly dependent on age group. [3] In multiple trauma patients with an Injury Severity Score >15, maxillofacial injury occurs in up to 16%, with a corresponding mortality rate of 10.5%. [4]

Anatomical Aspects

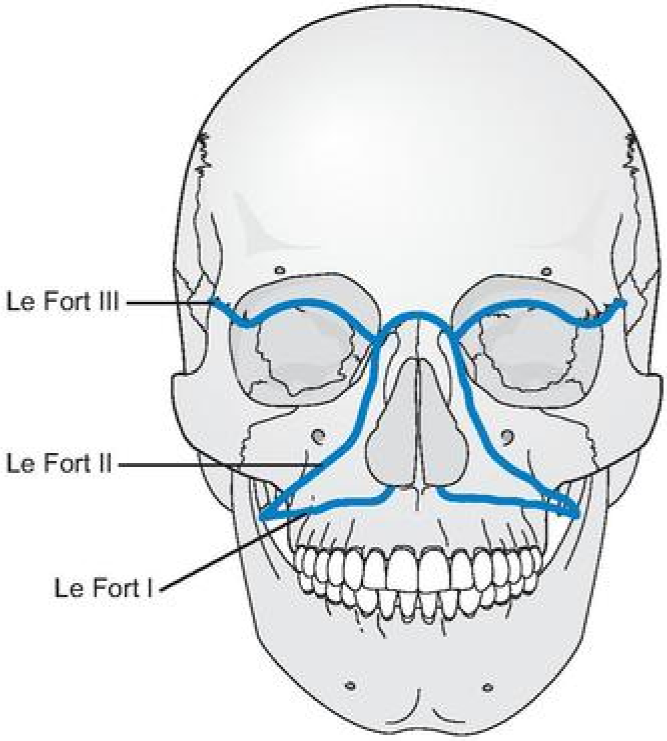
Fractures, haemorrhage, soft-tissue damage and oedema are the commonest manifestations of blunt facial trauma. The severity of facial injury is directly related to the velocity of force applied. Commonly, maxillofacial fractures involve the mid-face (including orbit) (71.5%), mandible (24.3%) and frontal bone (4.2%). [5]

Mandibular Fractures

The mandible is a unique horseshoe-shaped bone that is tubular and weakest where the cortices are thinnest. Most fractures occur at vulnerable points, regardless of the point of impact. [6] Common sites of fracture include the condyle, followed by parasymphysis and the angle. Multiple fractures are common (64%), [6] therefore where one fracture is evident, or clinically suspected, efforts should be made to identify or exclude a second fracture. Mandibular segments are often distracted owing to the action of the lower jaw muscles and even relatively minor displacement will manifest as malocclusion. [7]

Midfacial Fractures

The bones of the middle third of the face are relatively thin and poorly reinforced and thus are prone to fracture as the facial skeleton absorbs energy transmitted on impact. Compartments (nasal cavity, paranasal sinuses and orbits) within the bony framework collapse thereby absorbing energy and protecting the brain, spinal cord and other vital structures. [8] In high-energy injuries, multiple complex facial fractures usually result. French surgeon, Rene Le Fort, described several patterns of fracture in the facial skeleton and subsequently developed the Le Fort fracture classification (Fig. 79.1). [9] Le Fort fractures are perpendicular to the three main vertical buttresses of the facial skeleton – the nasomaxillary, zygomaticomaxillary, and critically, the pterygomaxillary ‘pillars’. Such fractures usually occur as mixed patterns, as impact to the face is rarely centred (e.g. right hemifacial Le Fort I and left hemifacial Le Fort II). Le Fort fractures are typically associated with high-energy injuries and clinicians should be aware that disjunction of the mid-face from the rest of the facial skeleton may be associated with airway obstruction, particularly when the patient is supine due to posterior movement of the soft palate against the tongue and posterior pharyngeal wall.



The frontal anatomical diagram of a human skull with three horizontal lines representing Le Fort fracture classifications. Each fracture line is outlined in blue and labelled on the left. Le Fort one runs horizontally above the teeth and through the maxilla. Le Fort two is a pyramidal-shaped line passing through the nasal bridge and maxilla, extending below the orbits. Le Fort three passes through the orbits and across the lateral sides of the face above the zygomatic arches. The diagram highlights the typical locations of facial fractures used in clinical categorisation.

FIG. 79.1 Le Fort classification of facial fractures.

Le Fort I

This fracture involves only the maxilla at the level of the nasal fossa. It follows a horizontal plane at the level of the nasal floor. The fracture separates the palate and maxillary dental arch from the remainder of the facial skeleton and is usually caused by direct impact with the lower maxilla or alveolus (i.e. tooth-bearing bone) of the upper jaw.

Le Fort II

The maxilla, nasal bones and naso-ethmoidal region of the orbit are involved, which results in a freely mobile, pyramidal-shaped portion of the mid-face. Fracture lines extend from the nasal bridge through the medial walls of the orbit, orbital floors and cross the zygomaticomaxillary buttresses. This pattern should alert the clinician to the risk of ocular or skull base injuries.

Le Fort III

This is known as craniofacial disjunction because the fracture line runs parallel to the base of the skull, separating the midfacial skeleton from the cranium. The fracture extends through the upper nasal bridge and naso-orbital ethmoidal (NOE) complex, through the lateral wall of the orbits and across the zygomatic arch. As these injuries involve craniofacial disjunction, they are frequently associated with base-of-skull injuries and cerebrospinal fluid (CSF) leaks.[10]

Temporomandibular Joint

Mechanical temporomandibular joint impairment may result from condylar or zygomatic arch fractures and can prevent jaw opening even after muscle relaxants have been administered. However, this presentation is uncommon and fractures through the condylar head, neck or subcondylar region of the mandible typically do not result in mechanical restriction to mouth opening.

Zygomatic, Orbital and Nasal Fractures

Zygomatic fractures account for approximately 30% of all facial bone fractures.[2,3] Simple, low-energy fractures involving the malar region often do not result in pure fractures of the zygomatic bone itself, but rather fractures typically propagate through suture lines (i.e. fronto-zygomatic suture and zygomatico-maxillary suture) and thus are often referred to as zygomaticomaxillary complex (ZMC) fractures.

Orbital injury is commonly associated with mid-face trauma. Clinicians should be aware that fractures in this region are frequently associated with ocular injury, therefore early eye examination is crucial to identify potentially sight-threatening injuries. [11] Orbital ‘blowout’ fracture, describes a fracture of the orbital floor without fracture of the adjacent bones. This is thought to occur when pressure directly applied to the globe is hydraulically transmitted to the interior bony structures. Disruption of the relatively thin orbital floor is the most common presentation of an orbital blowout fracture and may cause subconjunctival haemorrhage, enophthalmos, diplopia, ophthalmoplegia and infraorbital nerve hypoaesthesia. Ocular injuries are frequently missed and thus careful examination after a primary survey and resuscitation is required. Nasal fractures are very common, with epistaxis and septal haematoma being the primary concerns. Treatment of nasal fractures is typically delayed until the degree of deformity or functional impairment (i.e. obstruction) can be assessed.

Soft-Tissue Injuries

Abrasions, contusions and lacerations to the tongue, palate, pharynx, cheek, eyelids, nasolacrimal duct, ear, parotid duct and facial nerve can occur. Progressive oedema over 24–48 hours may be substantial resulting in distortion of soft tissues. Patency of an initially unobstructed airway may become compromised during this period and semi-elective intubation should be considered in cases thought to be at high risk.

Associated Injuries

More than half of all patients with maxillofacial injuries will have other injuries and these are listed below.

Basilar Skull Fracture

The anterior cranial fossa is often involved in craniofacial injuries. Fractures involving the frontal bone, frontal sinus, NOE complex or frontoorbital complex result in bone defects in the skull base and may result in CSF leak. The clinical finding of CSF rhinorrhoea is not specifically diagnostic for anterior cranial fossa injury as temporal bone fracture-related CSF leak also discharges into the nose via the Eustachian tube.[12] Similarly, middle cranial fossa defects can produce rhinorrhoea via the sphenoid sinus. Most leaks are present within 1 week of injury. Meningitis secondary to mid-face fractures is uncommon, despite CSF leaks occurring in up to 25% of patients.[13]

Temporal bone fractures may also be associated with facial nerve weakness (CNVII) and hearing impairment (CNVIII) and therefore should be assessed when practical, with specialist input sought when detected. Pulsating exophthalmos and the presence of an orbital bruit may indicate a carotid-cavernous fistula, which may develop following fractures involving the skull base and orbit.

Head and Cervical Spine Injury

The incidence of head injury in those with maxillofacial trauma has been reported to be 15% for severe head injury, increasing to 80% if all grades of head injuries are included,[14,15] with around 8% requiring neurosurgical intervention.[16] Cervical spine injury has been reported in up to 11% of patients. The prevalence of cervical spine fracture with mandibular injury is 6.5%[17] and is attributed to forces exerted directly or indirectly from the facial skeleton to the neck. C1/C2 and C5–C7 are at particular risk.

The association between maxillofacial and cervical spine injury depends on the mechanism of injury. Falls and motor vehicle accidents are more likely to cause cervical injury than sporting injuries or assaults.

Other Injuries

In patients with severe maxillofacial trauma; thoracic trauma (∼40%), abdominal trauma (∼30%) and limb fractures (∼40%) are other common co-existent injuries.[14] Dental injuries are present in 15%–20% of patients with maxillofacial fractures.[18,19]

Assessment of Facial Injuries

The priorities are airway management, haemorrhage control and identification of other life-threatening injuries. Once the patient is stable, a formal assessment of the facial injuries can proceed.

History

Evaluation of facial fractures begins with a history of the trauma; as the mechanism of injury is important to determine the likelihood of other injuries.

Examination

Physical examination includes evaluation of deformity, visual impairment, facial asymmetry, malocclusion, nasal septal deviation/haematoma, CSF rhinorrhoea and the extent of jaw opening. Other signs associated with basal skull fracture also should be noted (haemotympanum, Battle's sign and raccoon eyes). Tenderness and mobility on palpation of the alveolar process and the infraorbital rim or frontozygomatic suture indicate the presence of a complex midfacial fracture. Naso-orbito-ethmoid disruption also can be established by bimanual palpation and 'bowstring test' (when the eyelid is pulled laterally and a lack of resistance or movement of the medial canthus is detected, indicating an underlying fracture or detachment of the canthal tendon). Visual acuity (in the conscious patient), corneal integrity and pupillary reflexes, as well as eye movements (in particular, evaluation of upward movements in orbital blowout fracture), should be assessed early and thoroughly. Children are at high risk of 'trapdoor' orbital fractures compared to adults. A trapdoor fracture occurs when the disrupted orbital bone fragments cause entrapment of extraocular muscle (usually the inferior rectus) and may present with reduced upward gaze or oculocardiac symptoms such as nausea, vomiting or arrhythmia (such as bradycardia). This requires urgent surgical release to avoid long-term motility disturbance of the globe. Facial nerve function should also be assessed if possible. The presence of pulsatile exophthalmos and bruit over the orbit may indicate a carotid-cavernous fistula.

Investigation

Computed tomography (CT) scanning, especially with three-dimensional reconstruction, is the preferred imaging modality.[20] In addition to bony injury, fluid in the paranasal sinuses, optic nerve integrity, orbital contents, the brain, upper cervical spine and associated areas can be assessed concurrently. Other investigations, such as colour Doppler ultrasound studies, CT angiography or standard angiography of the great vessels in the neck, may be required to exclude carotid dissection or carotid-cavernous fistulae. Nasal discharge should be tested for β_2-transferrin to confirm the presence of a CSF leak.[21]

Airway Management

Airway management in maxillofacial injury is potentially complex owing to multiple concurrent compromising factors (Table 79.1).

Table 79.1

TMJ , Temporomandibular joint.

Immediate Priorities

- Assess and monitor for signs of airway obstruction whilst maintaining cervical spine precautions
- Clear airway, assist respiration
- Provide high-flow oxygen
- Definitive airway intervention

An initially unobstructed airway may become compromised as oedema can progress in the initial hours after injury. Careful monitoring in an intensive care or high-dependency unit is essential. Maintaining the head-up position and the use of humidified oxygen may lessen the likelihood of later airway compromise. Sudden obstruction may occur with clot dislodgement and inhalation. Signs of partial obstruction include noisy breathing, stridor, intercostal or supraclavicular recession and restlessness.

Occasionally, patients may assume positions that lessen airway obstruction (e.g. sitting forward or even prone). Simple measures, such as suction and clearing the airway and insertion of an oropharyngeal airway, may suffice.

In midfacial injuries, anterior digital traction on the mobile palatal segment may relieve obstruction. Bag and mask ventilation may be difficult owing to distorted anatomy, and this should be borne in mind when a decision to intubate is made. Failure of these simple manoeuvres necessitates definitive airway management.

Techniques

Facilities to perform a surgical airway or emergency front-of-neck access must be available prior to intubation. The chosen technique for securing the airway depends on the presence of airway obstruction and the likelihood of difficult direct laryngoscopy (extent of jaw opening, gross anatomical distortion and swelling, bleeding, operator experience). In a combative patient, or if urgent intubation is necessary, a rapid sequence induction can be used. If direct laryngoscopy is likely to be difficult or impossible, spontaneous respiration must be maintained and intubation carried out under local anaesthesia or light sedation. The orotracheal route for intubation is the route of choice in the presence or suspicion of a basal skull fracture.

If cervical spine injury is present or suspected, in-line stabilisation is mandatory. A variety of intubation techniques can be used, for example, direct laryngoscopy, awake fibre-optic-guided laryngoscopy or video laryngoscopy. [22] The operator should use the technique with which he/she is most comfortable. Excessive bleeding or debris may render fibre optic techniques difficult.

Failure to intubate and ventilate in the presence of airway obstruction necessitates insertion of a laryngeal mask and if ventilation is not established then emergency cricothyroidotomy should be performed. Formal tracheostomy may be required in those likely to need prolonged ventilatory support or in circumstances where multiple surgical procedures are likely to be needed and repeated endotracheal intubation is deemed to be high risk (e.g. multiple facial fractures combined with a head injury or multi-trauma patients) and is best performed as a semi-elective procedure in the operating room. [23]

Haemorrhage

Haemorrhage following maxillofacial injury is extremely common. Life-threatening bleeding is rare with an approximate incidence of 1%. [24] Most severe haemorrhage is associated with midfacial fractures, although soft-tissue lacerations of the face and scalp can also cause significant blood loss. Swallowing large quantities of blood may conceal haemorrhage and predispose to vomiting and aspiration. [25]

The vascular origin of bleeding in facial trauma may be difficult to identify and control. Anatomically, the vascular supply to the maxillofacial region is derived from both the internal and external carotid arteries, with anastomoses occurring between them as well as across the midline of the face. The maxillary artery is often the primary source of oro-nasal bleeding and is a key contributor to the vascular supply of the midface. [23, 24, 26]

Frequently, the comminuted nature of maxillary fractures makes the detection of an exact site of vessel injury challenging. [23] Terminal branches of the ophthalmic artery, a branch of the internal carotid artery, such as the anterior and posterior ethmoidal arteries, as well as lacrimal and zygomatic branches may contribute to bleeding.

The priority is to secure the airway as required. Direct pressure and aggressive packing to open bleeding wounds, nasal cavities and oropharyngeal cavities is then required. [27] Anterior or posterior nasopharyngeal packs are often effective at reducing blood loss. Foley catheters passed into the posterior nasopharynx with the balloons filled with air may stem blood loss. These can be used as a second-line option but may displace fractures further and should be used with extreme caution in patients with presumed or confirmed skull base fractures. If not already administered, tranexamic acid may be beneficial in the setting of maxillofacial trauma. [28] Permissive hypotension in these patients is controversial due to the high rate of concomitant head injuries. [27] Surgical opinion should always be sought early regarding the appropriateness of angiographic versus operative intervention for persistent haemorrhage.

Angiographic embolisation has an increasing role as a first-line approach for life-threatening intractable bleeding with an 85% success rate reported.[24], [29] Operative intervention includes reduction and stabilisation of fractures and direct ligation of bleeding or feeding vessels.

Definitive Management

Definitive surgical management of facial fractures is generally delayed 7–14 days to allow swelling to subside. Surgery may be further delayed if a severe concomitant injury co-exists (e.g. ocular, head or thoracic injury). Early surgical intervention may be warranted if optic nerve compression is present. The use of high-dose steroids in optic nerve compression is controversial particularly if the patient has an associated traumatic brain injury, as limited data exists regarding its efficacy.[23], [30] Irrigation and debridement of open wounds, closure of facial lacerations and removal of foreign bodies must be undertaken as soon as is practicable, preferably within 24 hours.

The benefit of prophylactic antibiotics in CSF leak remains controversial and local protocols should be followed.[31] The need and optimal timing of operative intervention is still disputed but the recent trend is for conservative management due to high rates of spontaneous closure, with lumbar drain insertion for CSF leak rarely used in trauma settings.[31] Appropriate tetanus prophylaxis must be given.

The use of modern internal fixation techniques has significantly reduced the need for maxillo-mandibular fixation (MMF) following facial fracture repair. Patients with Le Fort-type injuries or high condylar TMJ fractures will often have guiding elastics placed to control the dental occlusion and it is advisable to keep scissors near the patient to cut the elastics should there be concerns regarding respiratory distress or vomiting. Submental intubation is an alternative to nasal intubation or tracheostomy in patients deemed unsuitable for nasal intubation.

Injuries to the Larynx and Trachea

Direct trauma to the airway is rare, typically accounting for less than 1% of traumatic injuries.[32,33] The bony protection afforded to the airway by the sternum and mandible and death from asphyxia at the accident scene account for the rarity of the injury presenting to hospital. Common associations with laryngotracheal injury include thoracic spine injury (15.5%), cervical spine injury (9%), closed head injury (8.5%), facial fractures (20.2%) and vascular injuries (11.3%); exact values vary depending on case series.[32,34]

Laryngotracheal injury can be classified as blunt or penetrating. Failure to recognise these injuries, their complications and specific pitfalls in airway management can be fatal.[35]

Mechanism of Injury

Blunt Injury

Common causes include motor vehicle accidents where the extended neck impacts the steering wheel or dashboard. The ‘clothes-line injury’ occurs when a cyclist or horse rider collides with a cable or wire causing direct injury to the upper airway. Assaults and strangulation account for the remainder of blunt injuries. Direct blows are more likely to injure the cartilages of the larynx, whereas flexion/extension injuries are most commonly associated with tracheal tears and laryngotracheal transection.[36] The larynx above the cricoid cartilage is injured in 35%, manifesting as oedema, contusions, haematomas, lacerations, avulsion and fracture dislocation, most commonly of the thyroid and arytenoid cartilages.

When the cricoid cartilage itself is injured, this may cause recurrent laryngeal nerve dysfunction. The cervical trachea is injured in 45%.[37] Tracheal transection most often occurs at the junction between the cricoid cartilage and trachea. Oedema, fluid and air dissecting within submucosal layers of the larynx and trachea may cause airway obstruction. Air in the soft tissues can cause epiglottic emphysema and narrowing of the supraglottic airway. Straining, talking and coughing may worsen oedema.

Penetrating Injury

Penetrating injuries usually result from stab or gunshot wounds. The anterior triangle of the neck is the most common site of entry. The cervical trachea is most commonly involved in stab wounds. Of patients with penetrating laryngotracheal trauma, 19% also have cervicothoracic vascular injury, 15% have an oesophageal injury and 34% have chest trauma. [32]

Approach to assessment of penetrating neck trauma

Traditionally the assessment and management of penetrating neck injuries has been based on the application of a zonal approach, to determine when surgical exploration was indicated. In this approach, zone II injuries (between the cricoid and the angle of the mandible) required mandatory surgical exploration. However, in recent years the 'no zone' approach has gained increasing support and has been shown to be a viable alternative to routine neck exploration. [38-41] The 'no zone' approach utilises the clinical presence of haemodynamic instability or other 'hard signs' (Box 79.1), rather than the site of injury, as an indication for immediate surgical exploration of a penetrating neck injury. [38] In cases where these signs are absent and the patient is stable, a high-resolution CT angiogram should be performed with directed angiography, laryngoscopy, bronchoscopy and oesophagoscopy as indicated by clinical and radiological findings.

Box 79.1

'No zone' approach to penetrating neck trauma

Presence of any 'hard sign' on clinical assessment is an indication for urgent surgical exploration [38,40] :

- Shock/haemodynamic instability
- Airway compromise (including stridor)
- Wound bubbling
- Extensive subcutaneous emphysema
- Inability to manage secretions
- Expanding/pulsatile neck haematoma

- Focal neurological deficit

Assessment of Airway Injury

Definitive investigation and management depend on the airway status and presence of associated injury. The degree of injury is not readily assessable on the basis of any one clinical symptom or sign (Box 79.2) and delayed diagnosis is common. Airway obstruction can be delayed and insidious, therefore frequent reassessment is required. The emphasis has moved towards CT scanning in the first instance in stable patients with laryngeal tenderness, endolaryngeal oedema and small haematomas. CT may demonstrate fracture of cartilages, haematomas and other injuries. Further investigation with fibre optic laryngotracheoscopy under local anaesthesia can be used to identify vocal cord dysfunction, integrity of the cartilaginous framework and laryngeal mucosa. Rigid laryngoscopy can be used when adequate visualisation is not achieved with the former. Pharyngo-oesophagoscopy, contrast studies, open exploration and angiography may be required to exclude aerodigestive tract and major vascular injuries (Table 79.2).

Box 79.2

Clinical features in laryngotracheal injury

Symptoms

Respiratory distress, stridor, noisy breathing
Neck tenderness or oedema
Hoarseness
Dysphonia
Cough
Dysphagia

Signs

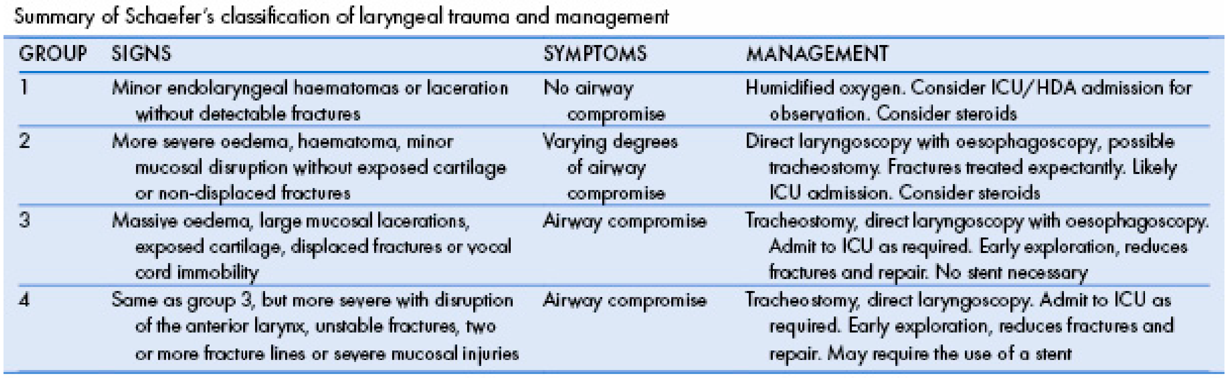
- Abnormal laryngeal contour
- Subcutaneous emphysema
- Cervical ecchymosis
- Haemoptysis

Investigations

- Plain radiography
  - Air in soft tissues
  - Pneumomediastinum
  - Pneumothorax
  - Cervical spine fracture
- CT scan
  - Cartilage and soft-tissue injury
  - Altered airway patency
- Laryngoscopy
  - Vocal paralysis
  - Mucosal or cartilage disruption
  - Haematoma
  - Laceration

CT , Computed tomography.

Table 79.2



Summary of Schaefer's classification of laryngeal trauma and management

GROUP	SIGNS	SYMPTOMS	MANAGEMENT
1	Minor endolaryngeal haematomas or laceration without detectable fractures	No airway compromise	Humidified oxygen. Consider ICU/HDA admission for observation. Consider steroids
2	More severe oedema, haematoma, minor mucosal disruption without exposed cartilage or non-displaced fractures	Varying degrees of airway compromise	Direct laryngoscopy with oesophagoscopy, possible tracheostomy. Fractures treated expectantly. Likely ICU admission. Consider steroids
3	Massive oedema, large mucosal lacerations, exposed cartilage, displaced fractures or vocal cord immobility	Airway compromise	Tracheostomy, direct laryngoscopy with oesophagoscopy. Admit to ICU as required. Early exploration, reduces fractures and repair. No stent necessary
4	Same as group 3, but more severe with disruption of the anterior larynx, unstable fractures, two or more fracture lines or severe mucosal injuries	Airway compromise	Tracheostomy, direct laryngoscopy. Admit to ICU as required. Early exploration, reduces fractures and repair. May require the use of a stent

HDA , High-dependency area; *ICU* , intensive care unit.

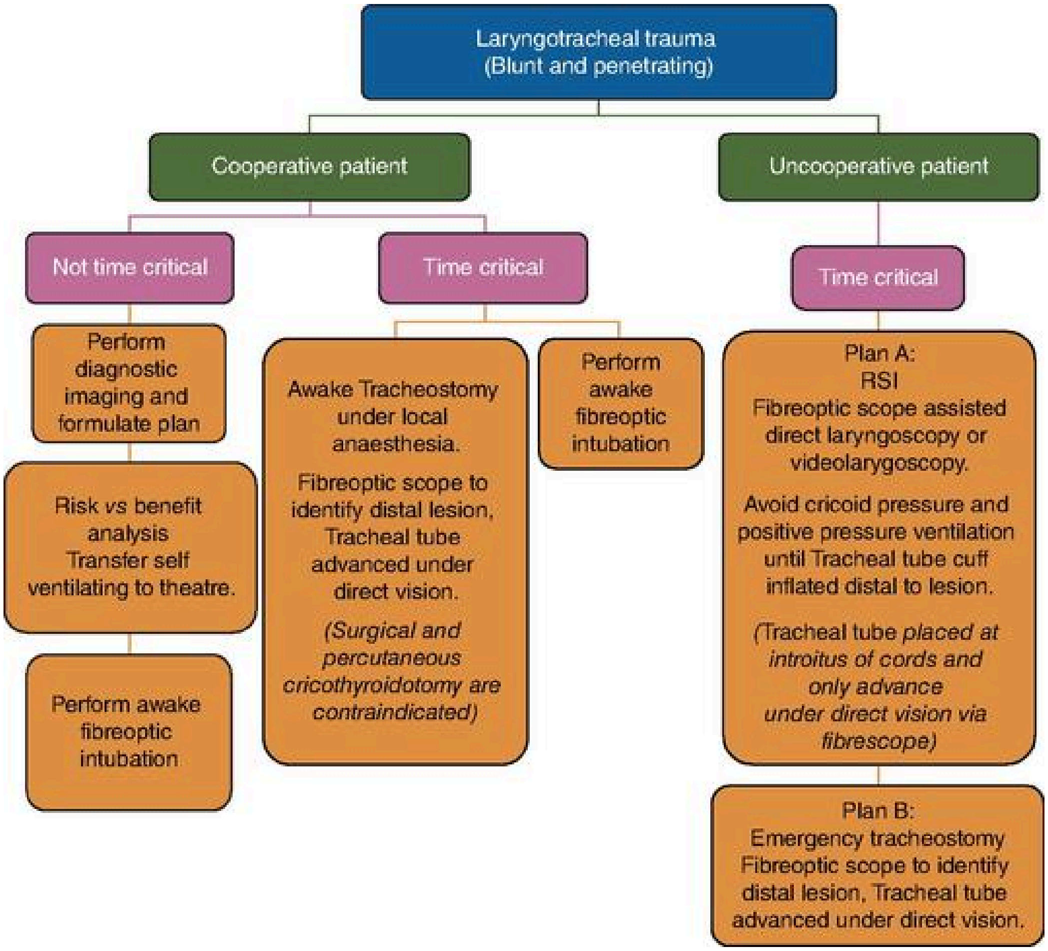
Airway Management

Up to three-quarters of patients with laryngotracheal injury require intubation. [33] The safest mode of intubation is via awake tracheostomy under local anaesthesia or fibre optic intubation either awake or asleep [42] (Fig. 79.2). Fibre optic intubation allows airway assessment and placement of the endotracheal tube distal to any tracheal defect. Blind intubation can lead to extending a tear, creating a false passage or disruption of the larynx or trachea. [42] Cricoid pressure can lead to laryngotracheal separation and is contraindicated. Positive-pressure ventilation can rapidly worsen air leaks and wherever possible the patient should maintain spontaneous respiration until a tube has been placed distal to the site of injury. Cricothyroidotomy is not recommended as it may compound laryngeal injury. In an emergency, gaping airway wounds (e.g. with tracheal transection) can be intubated under direct vision pending subsequent surgery.



Laryngotracheal trauma (Blunt and penetrating)
Cooperative patient
Uncooperative patient
Not time critical
Time critical
Time critical
Perform diagnostic imaging and formulate plan
Risk vs benefit analysis Transfer self ventilating to theatre.
Perform awake fibreoptic intubation
Awake Tracheostomy under local anaesthesia.
Fibreoptic scope to identify distal lesion, Tracheal tube advanced under direct vision.
(Surgical and percutaneous cricothyroidotomy are contraindicated)
Perform awake fibreoptic intubation
Plan A: RSI Fibreoptic scope assisted direct laryngoscopy or videolarygoscopy.
Avoid cricoid pressure and positive pressure ventilation until Tracheal tube cuff inflated distal to lesion.
(Tracheal tube placed at introitus of cords and only advance under direct vision via fibrescope)
Plan B: Emergency tracheostomy Fibreoptic scope to identify distal lesion, Tracheal tube advanced under direct vision.

The flowchart titled laryngotracheal trauma for blunt and penetrating begins with a division between cooperative and uncooperative patients. The cooperative patient section is further divided into non-time-critical and time-critical categories. For non-time-critical cases, the steps include performing diagnostic imaging, conducting risk versus benefit analysis, and performing awake fibreoptic intubation. For time-critical, it shows two options such as, awake tracheostomy under local anaesthesia using a fibreoptic scope and awake fibreoptic intubation. A note states that surgical and percutaneous cricothyroidotomy are not recommended. For uncooperative patients with time-critical needs, Plan A involves R S I with fibreoptic scope assisted direct laryngoscopy or videolaryngoscopy, avoiding cricoid pressure and positive pressure ventilation, and placing the tracheal tube only under direct vision. Plan B involves emergency tracheostomy using a fibreoptic scope to guide tube placement under direct vision.

FIG. 79.2 Mental model for airway management in laryngotracheal trauma. *RSI* , rapid sequence induction. (From Mercer SJ, Jones CP, Bridge M, et al. Systematic review of the anaesthetic management of non-iatrogenic acute adult airway trauma. BJA. 2016;117(S1):i49-i59.)

Surgical Management

In many case series, early repair (24–48 hours) leads to fewer complications. [43-45] It is indicated in laryngeal injuries when there are unstable fractures, significant mucosal injuries, haematomas, uncontrolled bleeding or damaged vocal cords. Delays in repair may lead to granulation and scar tissue formation, which can lead to laryngeal stenosis. [34] Laryngeal stenting is still controversial and the risks versus benefits of skeletal stability versus mucosal lining harm must be weighed up.

Chest injuries

Christopher Tobias Edmunds, Sarah McNeilly and Ubbo F. Wiersema

Chest injuries account for a quarter of all trauma deaths. Blunt trauma accounts for more than 90% of chest injuries in most civilian environments. Head injury is the leading cause of blunt traumatic death closely followed by exsanguination. Exsanguination from severe blunt trauma is typically due to rupture of the thoracic aorta and occurs in 10%–15% of patients suffering blunt trauma. [1], [2] Patients who survive transfer to the hospital may still have life-threatening chest injuries requiring immediate intervention. The majority of chest injuries can be managed with simple measures such as intercostal tube thoracostomy, oxygen therapy, analgesia and mechanical ventilation. [3–5] Surgery is required in less than 5% of thoracic injuries. [1] Tension pneumothorax, open pneumothorax or massive haemothorax require immediate intercostal tube drainage. Urgent thoracotomy is indicated for cardiac tamponade and massive haemothorax with ongoing bleeding. [4] Following the resuscitation phase, prolonged ventilatory support may be required for respiratory failure due to pulmonary contusions or rib fractures causing pain and impaired respiratory mechanics.

Immediate Management

Identification of chest injuries forms a core component of the primary survey of a patient with major trauma – both because immediate interventions can be lifesaving, and because restoration of respiratory and circulatory stability minimises secondary injury to extrathoracic organs, particularly in traumatic brain injury. [3] The mechanism of injury is predictive of the type and extent of injuries found, therefore an accurate history is key to guiding initial investigations and management. [6]

During the primary survey, the airway patency is ensured, oxygen is administered via face mask and respiration is assessed with support administered if required. The degree of circulatory compromise is determined, and obvious external bleeding is controlled. Large-bore intravenous access is gained, blood samples taken, and appropriate intravenous fluids commenced if necessary. Blood and blood products should be used if haemodynamic compromise is suspected to be due to blood loss. Intravenous analgesia is titrated to effect, with paracetamol, opiates and ketamine all commonly used. Complete exposure of the patient is important to facilitate a thorough examination of the chest and any immediate life-saving procedures necessary. With penetrating trauma, a full stab check should be undertaken, and all surface wounds must be located and documented. [4] There are four life-threatening chest injuries that may require immediate intervention:

- Tension pneumothorax
- Open (sucking) pneumothorax
- Massive haemothorax
- Pericardial tamponade

Interventions required during initial management are outlined in Box 80.1 .

Box 80.1

Interventions for the immediate management of chest trauma

Indications for intercostal drain insertion
    Tension pneumothorax
    Large haemothorax
Indications for urgent thoracotomy

    - Pericardial tamponade
    - Diaphragmatic rupture
    - Massive haemothorax with ongoing bleeding
- Indications for emergency thoracotomy
    - Witnessed loss of vital signs after penetrating trauma
- Indications for intubation and positive-pressure ventilation
    - Airway compromise
    - Gross hypoventilation and/or hypoxaemia (not attributable to pneumothorax)
    - Significant head injury

Endotracheal intubation and mechanical ventilation are indicated for the patient with a compromised airway, severe head injury or gross hypoventilation and/or hypoxaemia not attributable to chest trauma. Positive-pressure ventilation may cause the expansion of a simple pneumothorax and risks tension. Early tube thoracostomy should be considered in these patients. Haemodynamic instability should be anticipated during the induction of anaesthesia and preparations made. Rarely, an emergency cricothyroidotomy or tracheostomy is required when an airway obstruction cannot be bypassed by endotracheal intubation. A nasogastric or orogastric tube (if facial injuries or base of skull fracture are suspected) should be inserted to decompress the stomach after endotracheal intubation.

The severity of physiological derangement will dictate the timing of interventions and investigations necessary to confirm the injuries.

Imaging and Investigations

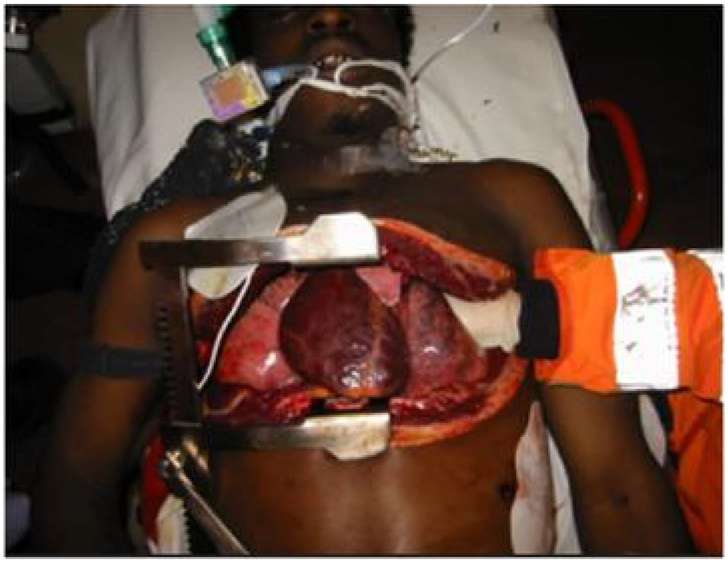
Detailed imaging of the thorax is crucial to identify injuries and guide management. This is most appropriately done with a computed tomography (CT) scan as part of whole-body imaging in polytrauma. The type of CT scan undertaken – either a dual phase or triple phase, will depend on the mechanism of injury and local protocols. A chest radiograph may be used initially to diagnose injuries needing immediate intervention before transfer for a CT scan (such as massive haemothorax).

Lung ultrasound can be completed faster than a chest radiograph and has significantly higher diagnostic accuracy for pneumothorax and haemothorax when performed by an experienced operator. However, it should only be used in the context of a positive finding and not as a rule-out test.[7–9] Subcostal ultrasonography of the heart to look for pericardial fluid forms part of the focused assessment with sonography for trauma (FAST) and should be performed with penetrating chest trauma, or if there is haemodynamic instability with blunt trauma.[4,7,9,10] An electrocardiogram (ECG) is important in the assessment of blunt cardiac injury.[4,11]

Cardiac Arrest and Emergency Thoracotomy

External cardiac massage is invariably unsuccessful in the trauma setting; it may cause further injury to intrathoracic structures and obstruct access to the patient for more potentially useful interventions such as bilateral pleural decompression in tension pneumothorax.[12] For patients with witnessed loss of vital signs after penetrating chest or upper abdominal trauma, emergency thoracotomy should be considered if suitably experienced medical personnel are available.[13–16] This is almost never successful for blunt trauma. The standard approach in the emergency setting is a clamshell thoracotomy (Fig. 80.1). This allows rapid access to the thoracic cavity to facilitate specific interventions[13,14,17–19]:

- Release of pericardial tamponade and control of cardiac bleeding
- Control of intrathoracic bleeding
- Control of massive broncho-venous air embolism
- Control of bronchopleural fistula with pulmonary hilar cross-clamping
- Temporary cross-clamping of the descending aorta, to redistribute blood volume to the brain, improve coronary perfusion and control intra-abdominal blood loss
- Internal cardiac massage



The clinical photo of an intubated adult patient lying on a stretcher with the chest cavity surgically opened. The rib cage is retracted using a rib spreader, exposing the heart centrally and the lungs on either side. A gloved medical team member is assisting in the procedure. An endotracheal tube is visible, connected to ventilation equipment. The patient is positioned supine with medical equipment and support personnel partially visible. The surgical opening reveals internal thoracic structures for emergency access.

FIG. 80.1 Clamshell thoracotomy. This surgical technique allows rapid access to the heart, mediastinum and thoracic cavity in penetrating trauma. It is designed for those who regularly manage major trauma patients but are not cardiothoracic surgeons; and equipment is easily available in the resuscitation room. This minimises delays in the patient receiving this potentially life-saving intervention. From Wise D, Davies G, Coats T, Lockey D, Hyde J, Good A. Emergency thoracotomy: "how to do it." *Emerg Med J.* 2005;22:22-24.

These temporising (damage control) measures are followed by rapid transfer to the operating room for completion of surgery which may include

[14], [15], [20]:

- Definitive repair of cardiac injury
- Pulmonary tractotomy, wedge resection or lobectomy/pneumonectomy for lung injury
- Repair or grafting of vascular injury

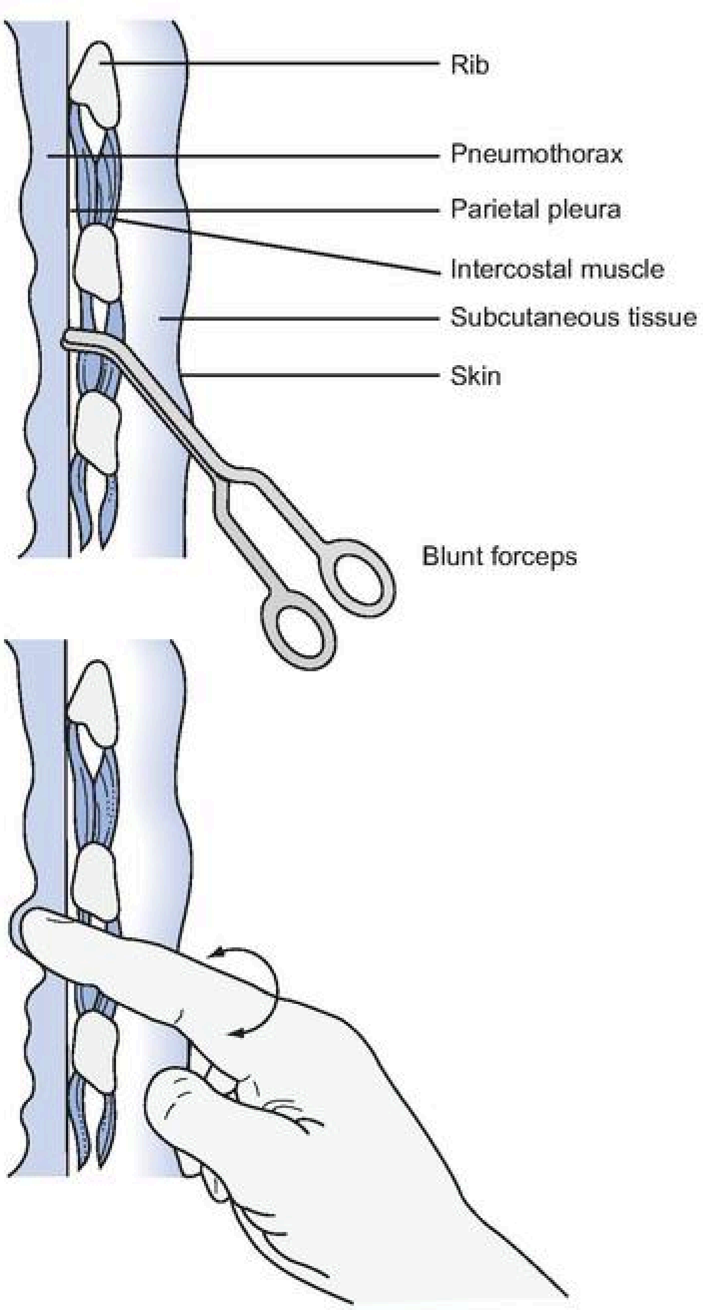
Postoperatively, the patient is admitted to the intensive care unit (ICU) for ongoing management.

Specific Injuries

After the primary survey and the addressing of initial life-threatening issues, a secondary survey and further imaging are performed to identify all injuries. Extrathoracic injuries causing haemodynamic instability (e.g. intra-abdominal bleeding) may need to be addressed before the completion of this phase. With the widespread availability of CT, CT angiography has become the primary imaging modality for the diagnosis of specific chest injuries. This is usually performed as part of a whole-body ‘pan scan’ (CT head, neck, chest, abdomen and pelvis) with an injection of intravenous contrast timed to provide aortic angiography. Endotracheal intubation and mechanical ventilation may be required to facilitate this (e.g. in the combative trauma patient with ethanol intoxication).[21] Chest CT is likely to identify injuries more accurately than chest radiography and will allow a nuanced, patient-specific management plan to be created.

Pneumothorax

Pneumothorax visible on the initial chest radiograph should be assessed and managed in the context of physiological signs as well as the size of the pneumothorax. A small pneumothorax can be safely managed conservatively with observation. A moderate-to-large pneumothorax can be treated with the insertion of an intercostal tube connected to an underwater seal drainage system (Fig. 80.2). A single-bottle drainage system without suction is usually adequate. There is no clinical consensus on the optimal management of moderate to large pneumothorax and it is the topic of ongoing studies. [22]

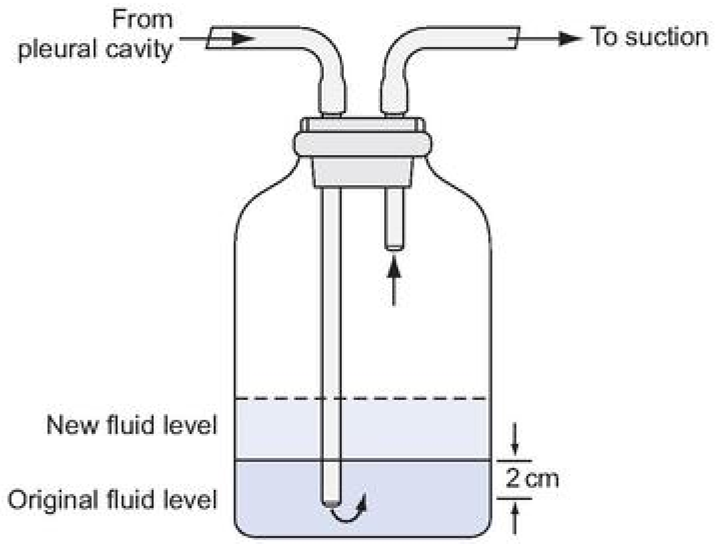


Rib
Pneumothorax
Parietal pleura
Intercostal muscle
Subcutaneous tissue
Skin
Blunt forceps

The two-part labelled medical diagram illustrates chest wall access for pneumothorax management. The top part shows a cross-sectional view of the chest with a pair of blunt forceps inserted through the skin, subcutaneous tissue, intercostal muscle, and parietal pleura to access the pleural cavity. Labels identify anatomical layers, including rib, pneumothorax, parietal pleura, intercostal muscle, subcutaneous tissue, and skin. The bottom part of the diagram shows a gloved hand with an extended index finger inserted into the same pleural space through the dissected chest wall layers. Both illustrations demonstrate a stepwise technique for creating access into the pleural cavity.

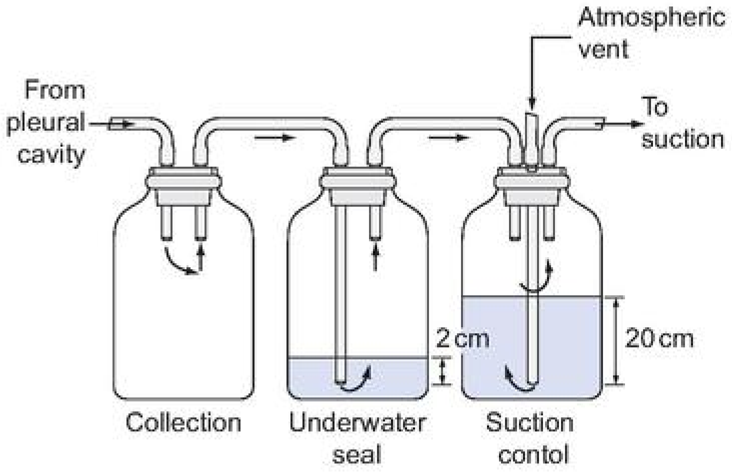
FIG. 80.2 Intercostal tube insertion. After sterile preparation and drape, 1% lidocaine is infiltrated in the mid-axillary line at the level of the nipple. A 2–3 cm transverse skin incision is made. Dissection is performed by blunt forceps down to the pleura passing just superior to the rib surface to avoid injury to neurovascular structures. A gloved finger is used to confirm the separation of lung from the chest wall. A large-bore (28–32 Fr) intercostal tube is inserted without a trocar and advanced in a postero-superior direction. Curved forceps clamped to the distal side hole of the tube can be used to guide the tube through the chest wall. The tube is immediately connected to an underwater seal drainage system (see Figs. 80.3 and 80.4) and checked for satisfactory drainage and tidal rise and fall in the fluid level with respiration. Non-absorbable sutures are used to seal the skin incision around the tube and secure the tube. The intrathoracic position of the tube is checked with a chest radiograph.

Low-pressure suction (20 cm H_2O) is applied if the pneumothorax fails to fully resolve (Fig. 80.3). A three-bottle system (or a commercially available three-in-one system) allows more accurate control of suction (Fig. 80.4). Use of antibiotics (to prevent empyema or pneumonia) is controversial, but contamination during intercostal tube insertion is common and a 24-hour course of a first-generation cephalosporin may be appropriate.[23], [24]



The labelled medical diagram shows a suction bottle used in pleural drainage. The bottle has two tubes at the top, one connected to the pleural cavity and the other to suction. A long vertical tube from the pleural cavity opening extends below the original fluid level inside the bottle. An upward arrow within this tube shows the air or fluid movement from the pleural cavity. A dashed line shows the new fluid level, which is 2 centimetres above the original fluid level.

FIG. 80.3 Single-bottle drainage system for haemopneumothorax. Air drainage will become more difficult if there is also fluid drainage, raising the fluid level in the bottle *(dashed line)* and increasing the depth of immersion of the hollow rod. This can be overcome by applying low-pressure suction (20 cm H_2O). *Arrows* indicate direction of airflow.



The labelled diagram shows a three-bottle chest drainage system arranged in sequence. The first bottle is labelled collection and is connected to the pleural cavity. Arrows show the flow of air or fluid into the bottle. The second bottle is labelled underwater seal and contains fluid with a vertical column reaching 2 centimetres. A tube from the first bottle enters below the fluid level, and another exits above it toward the third bottle. The third bottle is labelled suction control and contains a fluid column labelled at 20 centimetres. This bottle has an atmospheric vent at the top and a tube leading to suction. Arrows denote the directional flow across the system components.

FIG. 80.4 Three-bottle chest drainage system. The first bottle (connected to the intercostal tube) is a fluid collection chamber, the second functions as a one-way valve (underwater seal), and the third (connected to wall suction) limits the amount of suction applied. The level of suction is set by adjusting the depth of the atmospheric vent whilst ensuring that it bubbles continuously. Commercially available drainage systems function on the same principles as the three-bottle system. *Arrows* indicate direction of air flow.

Tension pneumothorax results from progressive accumulation of air in the pleural space, positive intrapleural pressure and cardiorespiratory collapse as a result. [25] Cardiac output is compromised by obstructed venous return; hypotension is prominent and may progress to cardiac arrest if not addressed rapidly. In spontaneously breathing patients the development of this pathology is typically slower than in patients undergoing positive-pressure ventilation. In both awake and ventilated patients, chest signs (ipsilateral hyper-expansion and decreased breath sounds, and tracheal deviation to the contralateral side) are not reliably present. [25]

If a tension pneumothorax is suspected clinically, an intercostal tube should be inserted immediately. Blunt dissection and insertion of a gloved finger into the pleural space allows rapid decompression of the tension, prior to intercostal tube insertion. [23] Needle decompression with a large-bore cannula inserted into the 2nd intercostal space in the midclavicular line or the 5th intercostal space in the mid-axillary line may be used to drain air more rapidly for patients in extremis. However, this is often of limited effectiveness due to the failure of the needle to reach the pleural space or kinking when the needle is removed from within the cannula. [23] It also carries associated morbidity including bleeding or injury to underlying structures. [24] Needle thoracostomy is usually followed by intercostal tube drainage but assessment of the pneumothorax size and physiological impact should be made before placement.

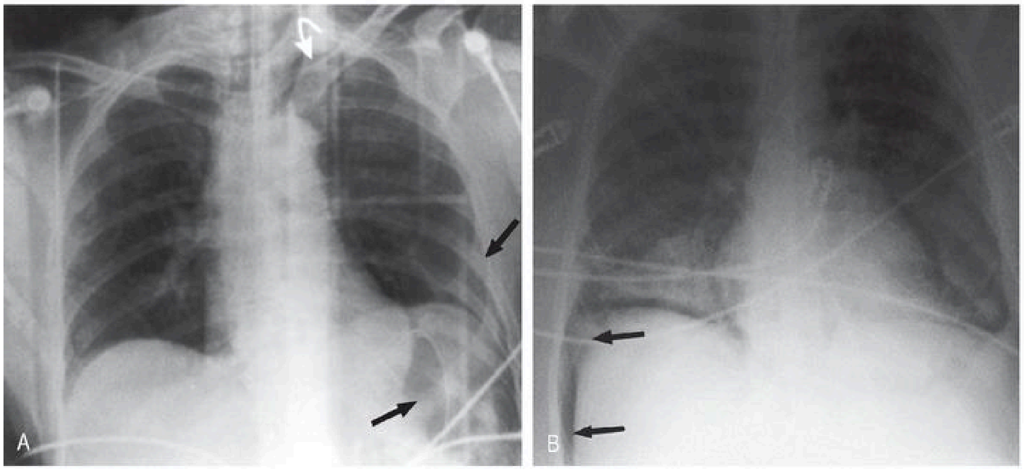
Open pneumothorax occurs when a chest wall defect allows direct communication of pneumothorax with the exterior, usually after penetrating trauma. Tension develops if air can enter but not exit through the defect. Initial treatment involves the application of an occlusive, non-adherent, square dressing sealed along three edges over the wound after sterile skin preparation. This allows air to escape but not enter through the wound. It should be followed by intercostal tube insertion at a site not immediately adjacent to the wound.

A simple pneumothorax may tension at any stage, especially with positive-pressure ventilation (see Box 80.2). A small pneumothorax may be difficult to detect on the initial chest radiograph. In the supine position, pleural air collects antero-inferiorly and is demonstrated radiologically by a deep sulcus sign or increased radiolucency of one side of the chest compared with the other (Fig. 80.5).[26]

Box 80.2

Causes of pneumothorax, subcutaneous emphysema and/or pneumomediastinum

Lung puncture
Tracheobronchial injury
Oesophageal injury
Facial or pharyngeal injury
Abdominal or retroperitoneal injury (air tracking up)



The side-by-side chest radiograph comparison is labelled A and B. In panel A, two arrows point to the right lower lung zone where a homogeneous opacity with a meniscus is seen. Additional tubes and lines are visible overlying the chest. In panel B, two arrows point to the lower zone of the left lung, where blunting of the costophrenic angle and diffuse haziness is seen. Both radiographs show pulmonary vascular markings and lung fields with different levels of clarity. Medical tubing is visible in both panels.

FIG. 80.5 (A) Moderate-sized left pneumothorax on supine chest radiograph. The visceral pleura is visible at the lung apex *(curved arrow)* . Hyperlucency is visible in the left lower chest *(straight arrows).* (B) Supine chest radiograph of right-sided deep sulcus sign *(arrows)* . From Miller LA. Chest wall, lung, and pleural space trauma. *Radiol Clin North Am.* 2006;44(2):213–224, viii.

Occult pneumothorax is defined as visible on chest CT, or upper slices of an abdominal CT, but not on plain radiograph. Drainage is not usually required but should be considered if prolonged surgery is anticipated or if there is significant cardiorespiratory compromise. With a conservative approach, the patient should be carefully monitored for signs of deterioration from the expansion of the pneumothorax.[17, 27]

Subcutaneous emphysema over the chest wall in a patient with blunt chest trauma is almost always associated with pneumothorax but should raise suspicion of other injuries (Box 80.2). The pneumothorax may not be visible on a chest radiograph, either because it is obscured by the emphysema, or because it has largely decompressed into subcutaneous tissues. An intercostal tube insertion should be considered.

Box 80.3

Chest radiograph signs of blunt aortic injury

If there is no associated fluid collection, the intercostal tube can be removed once the pneumothorax is no longer visible on the chest radiograph and there has been no air drained for at least 24 hours. Persistent air leak and incomplete drainage of pneumothorax after intercostal tube insertion should prompt investigation for tracheobronchial or oesophageal injury. However, the depth of the tube within the pleural space and tubing connections should be checked first to ensure that air is not being inadvertently entrained from outside the chest. Incomplete drainage with no air leak is usually due to tube misplacement or blockage of the intercostal tube.

Haemothorax

Haemothorax visible on the chest radiograph should be drained as completely as possible (see Fig. 80.1). The tube can be removed when there is <100 mL per 24-hour drainage and there has been a resolution on imaging. A small haemothorax (<300 mL) (visible on ultrasound or CT) may initially be managed conservatively but should be drained if it enlarges. Persistent opacity on the chest radiograph after tube placement should be further investigated to determine whether there is significant undrained fluid (see section “RETAINED HAEMOTHORAX AND EMPYEMA” later).

Massive haemothorax , defined as >1500 mL in volume, causes life-threatening circulatory compromise from hypovolaemia and vena caval compression, as well as hypoxaemia. This requires immediate tube drainage and consideration of surgical exploration. [17] Ongoing bleeding of >200 mL per hour or >600 mL over 6 hours (massive haemothorax equivalent) from a tube thoracostomy is an indication for further investigation and possibly surgical exploration or interventional radiology.

Pericardial Tamponade

Pericardial tamponade should be suspected in any patient with a gunshot wound to the chest, or stab wound to the chest or upper abdomen. It can rarely occur with blunt trauma and should be suspected if there is hypotension out of proportion to blood loss and distended neck veins. Pulsus paradoxus may be detected in the spontaneously breathing patient. The differential diagnosis also includes tension pneumothorax (more likely), cardiogenic shock from severe blunt cardiac injury, or inadequate resuscitation. Pericardial fluid can be detected with ultrasound via a subcostal view (as part of the FAST scan). [1]

Haemodynamically unstable patients should undergo thoracotomy. [13] , [14] Subxiphoid pericardiotomy can be performed in selected stable patients but may require conversion to open thoracotomy. Needle pericardiocentesis is rarely effective in the acute setting but may have a role in the drainage of delayed pericardial effusions following stab wounds. [13]

Blunt Aortic Injury

Blunt aortic injury usually occurs as a result of severe deceleration injury causing a tear at the junction between the fixed descending aortic isthmus and the mobile aortic arch, just distal to the origin of the left subclavian artery. [10] Less frequently the ascending aorta (or arch vessels) is injured by direct trauma. Most patients with blunt aortic injury die at the scene from complete aortic wall transection or associated injuries. Of those that reach the hospital, 90% will have a significant aortic injury and 50% of these will die within 24 hours.[10,28,29] Blunt aortic injuries may be classified by the anatomical layer affected[30–32]:

- Grade 1 – Intimal tear
- Grade 2 – Intramural hematoma
- Grade 3 – Pseudoaneurysm
- Grade 4 – Rupture

Aortic injury should be suspected if the mechanism of injury is suggestive of rapid deceleration, such as high-speed (greater than 50 km/h) motor vehicle or motorcycle collision, pedestrian hit by a vehicle or fall from a height greater than 3 m.[10,33] Clinical signs of significant aortic injury include unequal upper limb pulses, pseudocoarctation or interscapular murmur, but these are often absent.

Historically, chest radiography was the screening test of choice (to detect mediastinal haematoma), and aortic angiography was the diagnostic test for blunt aortic injury.[31] However, CT chest angiography is now the diagnostic test of choice. Transoesophageal echocardiography may be more appropriate in certain circumstances and is an alternative diagnostic tool.[32,34,35]

- *Chest radiograph:* features of blunt aortic injury are caused by distortion of the normal mediastinal contour by periaortic haemorrhage. A widened mediastinum (greater than 8 cm at the level of the aortic knuckle) is the principal finding (Box 80.3).[36] A supine chest radiograph accentuates mediastinal width and in the acute trauma setting is often of suboptimal quality. Measurement of left mediastinal width (>6 cm) or left mediastinal width to mediastinal width ratio (>0.6), may improve specificity.[34,37]
- *Chest CT angiography* provides sufficient resolution in multiple planes for CT to be used as the sole diagnostic test and has largely superseded other imaging modalities for the diagnosis of aortic injury.[29,32]

- *Transoesophageal echocardiography* is rapid and portable, making it suitable for the examination of an unstable patient (e.g. in the operating room). It provides high diagnostic accuracy for aortic injury and also allows examination for blunt cardiac injury. [34] However, imaging of the distal ascending aorta, proximal arch and major branches is limited. Thus if signs of mediastinal haematoma are detected, but an aortic injury is not identified, further diagnostic imaging is warranted. [32] It is contraindicated if an upper airway or oesophageal injury is suspected.
- *Interventional Radiology* offers an alternative that may be preferred if a branch vessel injury is suspected (Box 80.4). It can be time consuming and requires the transfer of the patient to the interventional radiography suite, making it potentially hazardous for the unstable patient. The use of hybrid suites may have some benefit in this decision making. [38]

Box 80.4

Signs of aortic branch vessel injury

Supraclavicular haematoma
Pulse discrepancy in arms
Brachial plexus palsy or stroke
Widened upper mediastinum on chest radiograph

Unstable grade 2–4 injuries require prompt surgical or thoracic endovascular aortic repair (TEVAR). [7], [29], [31], [39] Open surgical repair requires a left posterolateral thoracotomy and selective right-lung ventilation. Guidelines suggest delaying surgical repair in the stable patient where endovascular repair is not possible, this allows further resuscitation and the treatment of more pressing injuries and offers better outcomes. [40] The traditional direct repair (clamp and sew) has been associated with clamp-related ischaemia of distal organs and the spinal cord. Instead, techniques using a bypass circuit to actively perfuse the distal aorta past the injury repair site such as left atrial/right pulmonary vein to femoral artery bypass or the femoral vein to femoral artery bypass are now preferred.[7,31,39,41] These reduce the risk of postoperative paraplegia from spinal cord ischaemia but often require systemic heparinisation, which may exacerbate bleeding from other injuries. Sometimes a lumbar drain for cerebrospinal fluid (CSF) drainage is placed perioperatively to improve spinal cord perfusion and potentially reduce the incidence of paraplegia. Postoperatively, CSF is drained freely to maintain a CSF pressure of less than 10 mm Hg. The drain is removed after 3 days if there are no neurological complications. Surgery should be deferred, sometimes indefinitely, if severe associated injuries or co-morbidities make the operative risk unacceptably high. In such cases, TEVAR may still be feasible and in many institutions has become the primary method of aortic repair.[7,29,31,39] The procedure involves isolation of the injured section of the aorta by deployment of endoluminal stents, usually via cannulation of the iliac or femoral artery. Although less invasive and less time consuming than open repair, long-term outcome data are lacking, and complications may still occur.[7,29,31,39] Endoleaks can arise from incomplete exclusion of the site of injury, or inadequate apposition along the lesser curve of the aorta. Lesions immediately adjacent to the left subclavian artery may require stent coverage of the artery to fully exclude the site of injury. This may result in endoleak due to retrograde blood flow from the left subclavian artery, or ischaemia of the left upper limb or vertebral artery territory requiring left subclavian to left carotid artery grafting. Device collapse causing catastrophic aortic occlusion can occur if the endograft is oversized. With improvements in technology and operator experience, TEVAR now has a lower risk of mortality, paraplegia and blood loss than open surgery.[29] Serial follow-up imaging is recommended after TEVAR.[7,31]

In patients unfit for immediate intervention, beta blocker ± vasodilator therapy is given as tolerated to decrease aortic wall shear forces, aiming for a systolic blood pressure <100–120 mm Hg and heart rate <100 beats per minute. Delayed repair, after effective blood pressure control, has not been shown to worsen outcomes and may reduce the peri-procedural risk of paraplegia. [29]

Grade 1 aortic injury, with no associated periaortic haematoma or pseudoaneurysm on initial CT, can be managed conservatively, with serial imaging to monitor for progression. [30] Development of pseudoaneurysm, or periaortic haematoma should prompt consideration for TEVAR. [31]

Blunt Cardiac Injury

Blunt cardiac injury results from compression of the heart between the sternum and the spine, abrupt pressure changes within cardiac chambers, or deceleration shear injury. A wide spectrum of injuries have been described but may be classified according to the clinical sequelae and the need for intervention. [10]

- *Minor ECG and cardiac enzyme abnormalities:* Sinus tachycardia and premature beats are common but usually resolve within 24 hours without intervention. Raised troponin would warrant more investigation and monitoring as the risk of complication increases. [42]
- *Complex arrhythmias:* These may cause heart failure, or persistent hypotension, and may warrant antiarrhythmic therapy.
- *Free wall rupture:* This is usually fatal, but atrial rupture may present with haemopericardium ± tamponade. Immediate drainage and repair is required.
- *Heart failure:* this may develop from gross myocardial injury, septal rupture (causing left to right shunt), or valvular injury (causing regurgitation). The latter may not manifest until weeks later. Septal rupture and severe valvular injury require surgery. Myocardial dysfunction may require inotropic therapy.
- *Coronary artery injury:* This is very rare and ST-segment elevation on ECG is more likely to be due to a primary myocardial infarction.

All patients should have an ECG on admission. If this is normal and the patient is young, haemodynamically stable and has no history of cardiac disease, the risk of significant injury is very low and no further cardiac evaluation is required. Other patients should be monitored for late sequelae of significant cardiac injury (arrhythmia or heart failure).[10, 39] Patients who remain haemodynamically stable with only minor ECG changes, and who have a normal troponin level at 6–8 hours post injury, have a low risk of cardiac complications.[39]

Echocardiography is indicated for patients with hypotension unexplained by other injuries, heart failure or persistent arrhythmias.[4, 39] Undisplaced sternal fracture does not of itself warrant cardiac evaluation.[39, 43]

Tracheobronchial Injury

Blunt rupture of the trachea or bronchi results from a crush injury or rapid deceleration with the shearing of the airway between a fixed trachea and mobile lungs. The proximal right main bronchus is the most common site of injury.[4, 44] Large injuries present with respiratory distress, subcutaneous emphysema and haemoptysis (see Box 80.2).[45] The chest radiograph demonstrates pneumothorax and pneumomediastinum. Dramatic deterioration may follow the institution of positive-pressure ventilation. With smaller injuries, initial findings are often overshadowed by associated injuries with delay in diagnosis. Persistent pneumothorax with a large air leak, or recurrent pneumothoraces and pulmonary collapse, should prompt further investigation. Flexible bronchoscopy confirms the diagnosis and identifies the level of injury. Treatment is usually primary repair, although non-operative management has been described.[46] Temporising measures include placement of the endotracheal tube below the injury site under direct vision or placement of a dual-lumen tube for single-lung ventilation.[47] Late complications of either approach include post-obstructive pneumonia, empyema and bronchiectasis.[44]

With penetrating trauma, the cervical trachea is most commonly injured. Immediate management involves tracheal intubation (preferably with flexible bronchoscopy) with the cuff positioned distal to the tear to ablate the air leak. With a large neck wound, the endotracheal tube may need to be passed directly through the wound if the standard approach to laryngoscopy has been unsuccessful. [48]

Diaphragmatic Rupture and Diaphragmatic Paresis

The usual mechanism of diaphragmatic rupture is gross abdominal compression from direct vehicular intrusion. The risk of rupture is higher with lateral impact collisions, but not seat belt use. [49] Associated injuries are very common. [49] Rupture of the left hemidiaphragm is more common because the right hemidiaphragm is congenitally stronger and protected by the liver.

Symptoms (dyspnoea and chest pain) are non-specific. [50] Diagnostic chest radiograph findings are herniation of bowel into the thoracic cavity and nasogastric tube above the left hemidiaphragm however they have a low diagnostic accuracy with diaphragmatic injuries. CT scan with contrast has high diagnostic accuracy, which is increased with the reconstruction of the images. [51] When uncertainty persists magnetic resonance imaging or video-assisted thoracoscopic surgery (VATS) may be required. [52], [53] Prompt operative repair is important to prevent bowel incarceration or perforation. The choice of surgical approach (laparotomy or thoracotomy) is dictated by associated injuries and whether the mechanism is blunt or penetrating.

Traumatic phrenic nerve palsy, or postoperative diaphragmatic dysfunction, may go unrecognised whilst the patient is on mandatory positive-pressure ventilation. With the transition to spontaneous ventilation, paradoxical abdominal and chest wall movement, reduced vital capacity and difficulty weaning from ventilatory support become evident.

Oesophageal Injury

Rupture of the oesophagus from blunt trauma is rare. Penetrating trauma is more likely to injure the cervical portion of the oesophagus than the thoracic portion. Oesophageal perforation may rarely also result from attempted endotracheal intubation or gastric tube insertion during resuscitation of the trauma patient.[54] Clinical features of thoracic oesophageal injury include chest pain, dysphagia, pain on swallowing, haematemesis and subcutaneous emphysema (see Box 80.2). Chest radiograph findings include pneumothorax and/or hydrothorax, mediastinal emphysema, or widened mediastinum.[45] Suspected oesophageal injury from blunt trauma to the chest, or penetrating trauma to the chest or zone 1 of the neck, should be investigated with CT angiography.[17, 53] Peri-oesophageal air and/or fluid on CT should be investigated further with oesophagoscopy or oesophagography (gastrograffin swallow).[54] Oesophageal injuries are graded by the American Association for the Surgery of Trauma (AAST) classification:

- Grade I – Contusion/hematoma, partial thickness tear
- Grade II – Laceration less than 50%
- Grade III – Laceration greater than 50%
- Grade IV – Less than 2cm disruption of tissue or vasculature
- Grade V – Greater than 2cm disruption of tissue or vasculature.

Treatment is immediate surgical repair.[53] Postoperatively, nutrition is provided by the parenteral route until confirmation of healing via further imaging or direct visualisation. The timing to introduce enteral feed is very dependent on the location and type of injury.[54, 55] Occasionally, stable patients with a small, isolated thoracic oesophageal injury can be managed with oesophageal stenting, clips and thoracoscopic debridement and drainage.[54] Delayed recognition or repair (more than 12 hours post injury) leads to septic shock from mediastinal contamination. Extensive irrigation and drainage are then required, but postoperative complications are common.[54]

Pulmonary Injury

Pulmonary contusions are characterised by interstitial haemorrhage and oedema, with a secondary inflammatory reaction. Clinically there are signs of increased work of breathing, associated with impaired gas exchange and sometimes haemoptysis. The chest radiograph demonstrates patchy interstitial infiltrates, or consolidation not confined to anatomical segments. Gas exchange and radiographic findings may initially be unremarkable, with deterioration over the first 24–48 hours.[5,25] CT and lung ultrasound are more sensitive at detecting contusion, and quantification of the lung volume affected predicts the risk of acute respiratory distress syndrome (ARDS).[8,56,57] In the absence of complications (ARDS, pneumonia or aspiration) clinical and radiological recovery can be expected within 3–5 days.[25]

In patients who develop ARDS the principles of management are similar to those in ARDS that have developed from infective processes. Treatment is supportive with humidified oxygen therapy, and encouragement of deep breathing and coughing in the spontaneously breathing patient. High-quality analgesia is also important if the patient has concurrent rib fractures.[58,59] Non-invasive ventilation can be used in selected patients if gas exchange is poor. The use of high-flow nasal oxygenation is comparable to other non-invasive methods and may be better tolerated by some patients.[59,60] Intubation and mechanical ventilation are indicated for refractory hypoxaemia, progressive ventilatory failure, or if intubation is required for non-pulmonary reasons. Routine corticosteroids are not indicated. Antibiotics should be reserved for superimposed pneumonia.[5] After adequate initial fluid resuscitation, unnecessary further intravenous fluids should be avoided.

Pulmonary laceration occurs after blunt or penetrating trauma and causes disruption of the lung architecture with the formation of an air or blood-filled cavity. On chest radiography, lacerations are often initially obscured by adjacent contusion, but typically take many weeks to resolve and may be complicated by abscess formation or bronchopleural fistula.[25]

Bony Injuries

Half of all rib fractures are missed on plain chest radiography but should be suspected if there is localised tenderness over the chest wall. Patients with rib fractures are at high risk of having other traumatic injuries and developing complications several days later. These include pneumonia, ARDS, pleural effusion, pulmonary embolus, atelectasis and lobar collapse.

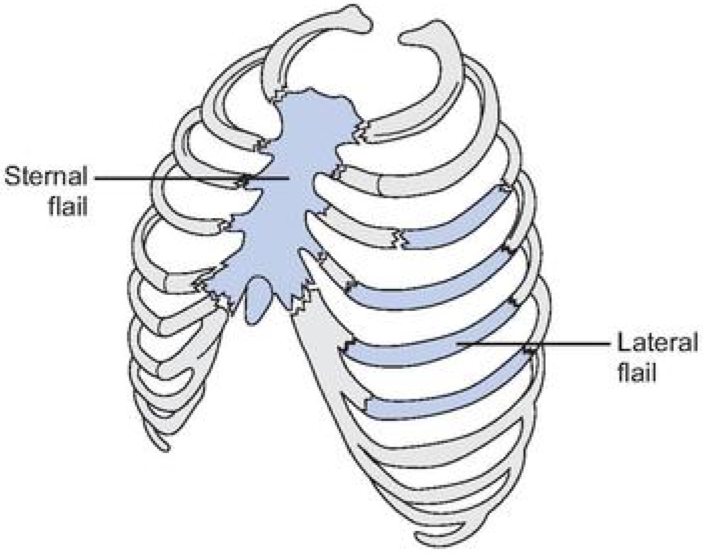
[60–62] This risk may not be clinically apparent initially, but deterioration in respiratory status over the next few days should be anticipated, especially in the elderly, smokers or patients with pre-existing pulmonary disease. Early aggressive management by a multi-disciplinary team using care bundles with a focus on optimal analgesia has been shown to improve outcomes.[60,61]

Consideration of early operative rib fixation in selected patients based on clearly defined pathways has shown benefits to these patients and avoids progressively escalating respiratory support.[60] First and second-rib fractures, scapula fractures and sternoclavicular dislocation are markers of high-energy trauma.[5]

Most sternal fractures occur in restrained occupants involved in frontal impact vehicular crashes. Associated thoracolumbar spine fractures are common.[43] Blunt cardiac injury should be suspected with displaced sternal fractures.[43]

Flail Chest

The fracture of at least two consecutive ribs in two or more places results in a flail segment with paradoxical movement of the chest wall during tidal breathing (Fig. 80.6).[5] Associated pulmonary contusions are often present. Younger patients with no other major injuries, no pulmonary co-morbidities and good analgesia can often be managed with non-invasive ventilation or oxygen therapy alone.[62] Deteriorating gas exchange and sputum retention are indications for intubation and mechanical ventilation. Prolonged ventilatory support is often not necessary in patients whose associated injuries and co-morbidities are not severe. Surgical stabilisation has been advocated for severe flails to reduce the duration of ventilation, although the optimal technique for surgical fixation remains uncertain.[60,63–65]



The labelled anatomical diagram of the anterior rib cage shows fractured segments associated with flail chest. The central portion of the sternum is shaded and labelled sternal flail, representing a segment of the sternum that moves independently. On the opposite side, a shaded section along the lateral aspect of the ribs is labelled lateral flail, representing multiple consecutive rib fractures creating a mobile segment. The rest of the rib cage and sternum are shown in unshaded outline.

FIG. 80.6 Types of flail chest. Modified from Wanek S, Mayberry JC. Blunt thoracic trauma: flail chest, pulmonary contusion, and blast injury. *Crit Care Clin.* 2004;20:71–81.

Extrapleural Haematoma

Traumatic extrapleural haemorrhage arises when chest wall bleeding does not enter the pleural space. [66] Chest radiography shows a parietal shadow that does not cause blunting of the costophrenic angle or shift with gravity.

A large haematoma should be evacuated with an intercostal tube or by thoracotomy.

Systemic Air Embolism

This is more frequent with penetrating injuries and is immediately life-threatening. The typical presentation is circulatory collapse after the institution of positive-pressure ventilation when the pulmonary air-space pressure exceeds pulmonary venous pressure (see Box 80.2). Focal neurological changes in the absence of head injury also suggest the diagnosis. Characteristic head CT findings have been described.[67]

When suspected, maintenance of spontaneous ventilation is preferred. If positive-pressure ventilation is necessary, an inspired oxygen concentration of 1.0 should be used, with ventilatory pressures and volumes reduced to a minimum. Selective lung ventilation, using a double-lumen endotracheal tube or bronchial blocker, and/or extra-corporeal membrane oxygenation (ECMO) should be considered.[67,68] However, urgent thoracotomy, with hilar clamping or lung isolation, is usually indicated.[17] Hyperbaric oxygen therapy has been used to treat cerebral air embolism but is often impractical.[67]

Complications and Intensive Care Unit Management

On admission to the ICU, rewarming, correction of coagulopathy and ongoing fluid resuscitation are often required. Management of coagulopathy and blood product resuscitation can be guided by the use of thrombelastography (TEG) or rotational thromboelastometry (ROTEM).[69]

Pericardial tamponade and persistent air leaks should be anticipated in post-thoracotomy patients.[16] A restrictive approach to fluid therapy is indicated for patients who have undergone lung surgery. However, care should be taken to ensure adequate fluid resuscitation. A judicious transfusion policy should be employed with all patients.[70]

As with other critically ill or injured patients, prophylactic measures against thromboembolism and upper gastrointestinal stress ulceration should be used. [71] Adequate nutrition is important to consider due to the hypermetabolic and catabolic responses. Timing of nutrition is crucial to reduce the incidence of sepsis and improve outcomes. [72]

Acute Respiratory Failure and Mechanical Ventilation

Respiratory complications are common. When acute lung injury occurs early after trauma, common causes include pulmonary contusion, aspiration, transfusion-related acute lung injury (TRALI) and prolonged shock or delayed resuscitation with severe systemic inflammatory response. Aspiration with persistent lobar collapse is an indication for bronchoscopy to exclude bronchial obstruction from particulate obstruction. When lung injury develops several days later, sepsis of either pulmonary or non-pulmonary origin is a more likely cause.

The approach to mechanical ventilation for intubated patients follows the same principles as with other critically ill patients:

- Patients with acute lung injury/ARDS should be ventilated with a lung-protective strategy. However, high positive end-expiratory pressure (PEEP) and permissive hypercapnia are relatively contraindicated if there is an associated head injury.
- Patients with pneumothorax or tracheobronchial injury should be managed with low PEEP, low peak airway pressures, and early transition to spontaneous ventilation if possible. This is sometimes challenging in the context of the specific leak and may require endobronchial isolation or isolated lung ventilation until the leak has healed.
- Patients with flail chest may benefit from the splinting effect of moderate levels of PEEP.
- Failure to wean from mechanical ventilation should raise suspicion of fluid overload, diaphragmatic injury, cardiac dysfunction or flail.

Select patients with hypoxaemia refractory to optimal mechanical ventilation may be supported with veno-venous ECMO.

Sputum Retention

Sputum retention leads to progressive pulmonary collapse, with impaired gas exchange, increased work of breathing and increased risk of infection. Smokers, or patients with pre-existing respiratory disease, are particularly at risk. In the spontaneously breathing patient, good analgesia and incentive spirometry to facilitate coughing and deep breathing can reduce risk. In the intubated and ventilated patient, humidification, tracheal suctioning and regular position changes are important. The role of a multi-disciplinary team and the input of physiotherapy is crucial to the progress of these patients in their care pathway and should be considered early.

Analgesia

High-quality analgesia is the mainstay of managing blunt chest trauma, alongside early mobilisation and physiotherapy. Numerous different analgesic regimens have been proposed, however, there is still a paucity of evidence as to the optimal regimen. Current recommendations include thoracic epidural analgesia and multi-modal analgesia. [73]

Thoracic epidural analgesia involves running a continuous infusion of local anaesthetic with or without an opiate through a catheter into the thoracic epidural space. Many consider this the gold standard for treating pain from rib fractures and other blunt thoracic trauma however their value has been questioned. [74] A recent meta-analysis demonstrated superior analgesia with an epidural compared to other methods but failed to demonstrate any benefit on other outcome measures such as length of stay or duration of mechanical ventilation. [75] There is a low risk of complications however these may be significant (for example epidural haematoma). [76] Thoracic epidural is also contraindicated in many trauma patients including those with concurrent spinal injury, vertebral body fracture or coagulopathy.

Multi-modal analgesia combines opioids with non-opioid analgesics such as paracetamol and non-steroidal anti-inflammatory agents.[60] Depending on individual patient circumstances, these can be delivered enterally or parenterally. In alert, cooperative patients, patient-controlled analgesia with intravenous boluses of morphine or fentanyl may be used. If there is an element of neuropathic pain a gabapentinoid can be added though evidence is lacking.[60] For difficult-to-treat pain ketamine either orally or as an intravenous infusion may be used also.

Novel facial plane blocks allow a local anaesthetic infusion to be delivered via a catheter into a tissue plane through which a nerve passes. They are a useful alternative to a thoracic epidural – particularly in those patients where an epidural is contraindicated (for example therapeutic anticoagulation). There is increasing evidence of the use of serratus anterior plane and erector spinae plane blocks in blunt thoracic trauma, particularly rib fractures, though high-quality trials with large numbers of patients are lacking.[77–79]

Pneumonia

Sepsis is the principal cause of late death after major trauma. Breach of the skin surface barrier, devitalised tissues and the presence of invasive drains and catheters make the trauma patient especially prone to bacterial invasion. In the chest-injured patient, pulmonary contusion, emergency intubation, shock, blood transfusion and the presence of extrathoracic injuries increase the risk of nosocomial pneumonia.

Early-onset pneumonia (within the first few days of hospitalisation) may result from aspiration at the time of injury, particularly after head injury. Common pathogens are *Haemophilus influenzae* , *Pneumococcus* and anaerobes. Later-onset nosocomial pneumonia is more likely to be due to aerobic Gram-negative bacilli and *Staphylococcus aureus* .

The diagnosis of pneumonia is suspected if there are new or progressive infiltrates on the chest radiographs and deterioration in respiratory status. However, new infiltrates may also be caused by pulmonary contusion, pleural fluid collections, atelectasis, aspiration and pulmonary oedema.

Infection is supported by the presence of purulent sputum, new fever and leucocytosis. Confirmation depends on the culture of tracheal aspirate or bronchoscopic samples.[80]

Antibiotic therapy should be targeted at causative organisms. Prompt empirical antibiotics should be started in unstable patients, with re-evaluation at 48–72 hours.

Preventative measures include careful hand cleansing, reduced duration of intubation and ventilation, semi-recumbent position, enteral nutrition, avoidance of excessive sedation or hyperglycaemia, and avoidance of prolonged prophylactic antibiotics.[80]

Retained Haemothorax and Empyema

Haemothorax that is not adequately drained within a few days becomes clotted and unable to drain via intercostal tube. The clot becomes organised and fibrosed with progressive pleural thickening (fibrothorax). This results in loss of lung volume, impaired pulmonary compliance and increased risk of empyema formation. Patients with persistent opacity on chest radiographs after intercostal tube placement should undergo further imaging to determine whether a significant retained haemothorax is present.[13, 27] Small haemothoraces (<300 mL) in clinically stable patients where the pleural cavity has not been breached may be observed. However, in the presence of respiratory compromise, suspected empyema, or retained haemothorax over 300 mL, further intervention is required. Several management options are available, but complete drainage should be achieved within 3–7 days, before the development of fibrothorax or empyema.

If the initial intercostal tube is poorly positioned, or blocked, a second tube may be placed through a different skin incision, preferably under radiological guidance. In other circumstances, a second intercostal tube should be avoided because of the increased risk of empyema formation and a high failure rate.[13, 27, 81]

If the initial intercostal tube remains patent, evacuation of the retained haemothorax can be attempted with intrapleural administration of a fibrinolytic agent such as tissue plasminogen activator (TPA), after the exclusion of a bleeding diathesis or intrathoracic organ injury. [27, 82] Fibrinolysis is most likely to be successful if attempted within 3 days of initial haemothorax. [27, 82] Intrapleural administration of a combination of TPA and DNase has been advocated to assist drainage of early retained empyema but has not been evaluated for retained haemothorax and may increase the risk of bleeding. [83]

VATS is the recommended surgical approach in haemodynamically stable patients who can tolerate single-lung ventilation. [13, 27, 53, 81, 84] Failure of these techniques, or empyema formation, requires formal thoracotomy +/− decortication. [84] VATS and thoracotomy allow direct inspection for a missed pulmonary, diaphragmatic or oesophageal injury. [53]

Patients who did not require initial intercostal tube drainage, but who subsequently develop respiratory compromise or opacification on chest radiograph, should have repeat imaging to look for delayed haemothorax. This should also prompt reconsideration of an occult injury to the diaphragm or an intrathoracic organ.

Fat Embolism Syndrome

Fat embolism is very common in patients with long-bone fractures and frequently causes oxygen desaturation, which may be severe and prolonged in patients with parenchymal lung injury. [85] However, fat embolism *syndrome* , with pulmonary, neurological and cutaneous sequelae, is rare. The treatment of fat embolism is supportive, but early resuscitation and fracture stabilisation are important preventative measures. [86] Early (<24 hours) intramedullary nailing is the fixation method of choice, resulting in fewer orthopaedic complications than other fixation methods, and fewer pulmonary complications than delayed surgery. [87, 88] However, internal fixation may provoke further fat embolism, require a longer operative time and result in more blood loss than external fixation. [87] Thus, in severely chest-injured patients, temporary stabilisation using external fixation with intramedullary nailing several days later is preferred. [87]

Prognosis

Risk of death and length of intensive care stay depends on the severity of chest injury, the extent of extrathoracic injuries and pre-existing co-morbidities.[3], [88] Initial physiological markers that predict adverse outcomes are a low Glasgow Coma Scale score, hypotension and a high respiratory rate. In patients with severe blunt trauma, the mortality is significantly higher with bilateral than with unilateral chest injuries and depends more on the extent of parenchymal lung injury than the extent of chest wall injury.[89] Older age correlates strongly with worse outcomes, even though the elderly are more likely to suffer rib fractures than parenchymal lung injury.[88–90] In the elderly, the risk of death or pneumonia increases with each additional rib fractured.

The use of scoring systems in the emergency department can help prognosticate for patients with blunt chest trauma which aids management and optimal place of care in the hospital.[60], [89]

Spinal injuries

Oliver James Flower and Sumesh Arora

Introduction

Spinal cord injury (SCI) has immense consequences for patients, their families, healthcare resources and society. Initial management of SCI and prevention of secondary injury may make substantial differences to long-term functional outcomes. SCI is best managed in specialised spinal injury units, with specialist medical, nursing and allied health expertise.[1,2] Despite their disability, survivors often report high levels of life satisfaction, years after their injury.[3] Non-traumatic SCI, from a broad range of aetiologies, shares many clinical and pathological features with traumatic SCI. However, as the specific differences in managing non-traumatic SCI are beyond the scope of this chapter, this focus is on traumatic SCI.

Epidemiology

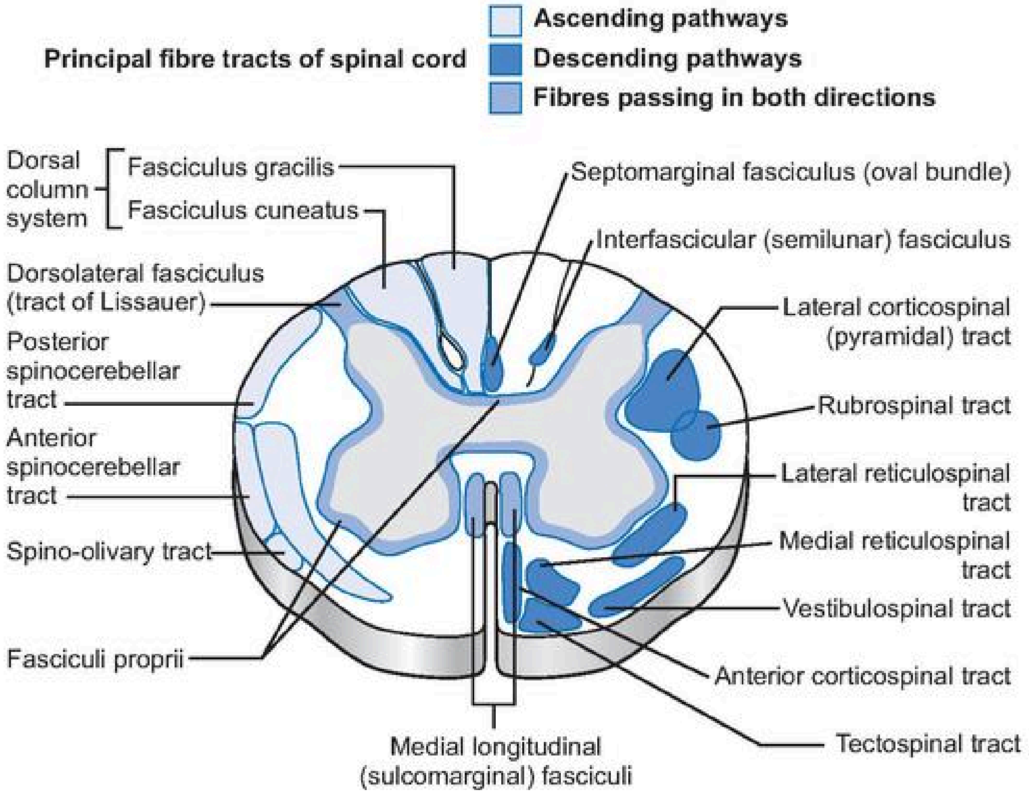
Globally, there are approximately 1 million new spinal cord injuries per year and 20 million people living with SCI. The incidence is higher in males and rises with age. Falls have overtaken road accidents as the commonest cause, followed by conflict/interpersonal violence in low-middle-income countries and sports-related injuries in high-income countries. Pre-existing spinal pathologies, such as spinal canal stenosis, ossification of posterior longitudinal ligament, osteoporosis and ankylosing spondylitis, increase the risk of SCI from relatively minor trauma. Over 50% of SCIs are cervical.[4,5]

Pathogenesis

Applied Anatomy and Physiology

The spinal cord extends from the foramen magnum to approximately the L1-L2 level. The conical lower end of the spinal cord is called the conus medullaris, from which a filament of fibrous tissue, known as filum terminale, continues inferiorly. The cauda equina refers to the bundle of spinal nerves, from the lumbo-sacral segments, that continue below the spinal cord. Compared to the spinal cord in the cervical and thoracic regions, the cauda equina is less susceptible to injury due to a relatively larger canal size in the lumbar region. [6] Corresponding to each intervertebral level, dorsal and ventral roots exit the spinal cord and join within the dural sac to form the spinal nerve. The spinal nerves run caudally within the spinal column until they reach the corresponding vertebral levels, then exit through the spinal foramen. During development, the vertebral column elongates more than the spinal cord, so there is an increasing discrepancy between the anatomical level of spinal cord segments and their corresponding vertebrae caudally.

The sympathetic nerve supply originates from the intermediolateral column of segments T1-L2. The parasympathetic outflow originates from S2 to S4 level and supplies the pelvic viscera. A cross-section of the spinal cord is shown in Fig. 81.1 .



Principal fibre tracts of spinal cord
Ascending pathways
Descending pathways
Fibres passing in both directions
Dorsal column system
Fasciculus gracilis
Fasciculus cuneatus
Dorsolateral fasciculus (tract of Lissauer)
Posterior spinocerebellar tract
Anterior spinocerebellar tract
Spino-olivary tract
Fasciculi proprii
Septomarginal fasciculus (oval bundle)
Interfascicular (semilunar) fasciculus
Lateral corticospinal (pyramidal) tract
Rubrospinal tract
Lateral reticulospinal tract
Medial reticulospinal tract
Vestibulospinal tract
Anterior corticospinal tract
Tectospinal tract
Medial longitudinal (sulcomarginal) fasciculi

The labelled diagram of a transverse section of the spinal cord shows the principal fibre tracts. The diagram uses three colours to show ascending pathways, descending pathways, and fibres passing in both directions. The dorsal column system includes fasciculus gracilis and fasciculus cuneatus. Other ascending tracts labelled are the dorsolateral fasciculus, posterior spinocerebellar tract, anterior spinocerebellar tract, and spino-olivary tract. Descending pathways include the lateral corticospinal tract, rubrospinal tract, lateral reticulospinal tract, medial reticulospinal tract, vestibulospinal tract, anterior corticospinal tract, and tectospinal tract. Bidirectional tracts labeled include septomarginal fasciculus, interfascicular fasciculus, fasciculi proprii, and medial longitudinal fasciculus. Each tract is labelled at its location within the white matter surrounding the central gray matter.

FIG. 81.1 Cross-section of the spinal cord. (From Principal Tracts of Spinal Cord, Image ID: 60477, published in Rubin M, Safdieh JE. Gross anatomy of the brain and spinal cord. In: *Netter's Concise Neuroanatomy* . Saunders; 2007:49.)

Spinal Cord Injury

The pathophysiology of SCI is biphasic, with primary and secondary phases.

Primary Injury

Direct mechanical injury may produce focal compression, haematoma, laceration or traction injury to the cord. Actual transection is unusual. Ischaemic injury may result from injury to the segmental spinal arterial supply. Initial pathological changes include the traumatic severing of axons, blood vessels and cell membranes.[7], [8]

Secondary Injury

Local ischaemia begins at the site of injury, extending progressively, over several hours, from the site of injury in both directions. There is a loss of autoregulation of blood flow to the spinal cord, often complicated by arterial hypotension in high SCI. Other mechanisms that may contribute to the secondary injury include the release of reactive oxygen species, eicosanoids, calcium, proteases, phospholipases and excitotoxic neurotransmitters (e.g. glutamate).[7], [8]

Petechial haemorrhages begin in the grey matter, progress over hours and may result in significant haemorrhage into the cord. There is oedema, cellular chromatolysis and vacuolation and ultimately neuronal necrosis. Apoptosis, especially of oligodendrocytes, also occurs.[7] In the white matter, vasogenic oedema, axonal degeneration and demyelination follow. Polymorphs infiltrate the haemorrhagic areas. Late coagulative necrosis and cavitation subsequently take place.[9]

Initial Assessment and Management

Early management of SCI should focus on the prevention of secondary injury and provide optimum conditions for neurological recovery. This is achieved by immobilisation until the spine is stable, prevention of hypoxia, defending blood pressure and avoiding metabolic abnormalities.

In general, the principles of managing severe trauma are outlined in Chapter 77 . Resuscitation must occur simultaneously with evaluation, initial investigations and management. The specific considerations in the acute setting are outlined in Table 81.1 .

Table 81.1

Acute issues following spinal cord injury

ISSUE	PATHOPHYSIOLOGY RELEVANT TO SCI	MANAGEMENT
Need for intubation	Paralysis of muscles of respiration below NLI Increased secretions and bronchospasm from loss of sympathetic innervation	Consider intubation for Respiratory failure Decreased level of consciousness Transport to another hospital or for imaging Surgical intervention
Intubation	Excessive movement of neck in unstable cervical injury may cause further spinal cord damage	If intubation is urgent, rapid sequence induction and intubation with manual in-line stabilisation Minimise neck movement Video laryngoscopy improves view and minimises movement Consider awake fibre-optic intubation if time and expertise available
Hypotension	Loss of vasomotor tone below NLI Bradycardia for NLI above T1 Traumatic abdominal or long-bone haemorrhage presents differently in patients insensate below the NLI	Must exclude hypovolaemia/haemorrhagic shock Vasoplegia and bradycardia from SCI causes neurogenic distributive shock Give fluids initially Have low threshold for inserting central line and using vasopressors

ISSUE	PATHOPHYSIOLOGY RELEVANT TO SCI	MANAGEMENT
		Consider targeting a MAP of 85 mm Hg to maintain spinal cord perfusion
Bradycardia	Loss of cardiac sympathetic innervation (T1-T4)	May require anticholinergics (e.g. atropine), chronotropics (e.g. isoprenaline) or pacing
Neurological examination	NLI and ASIA grade may be difficult to assess once patient is intubated	Obtain NLI and ASIA grade if patient alert, before sedation or intubation
Medications	Sedation may prevent accurate assessment of neurological status	Use short-acting sedatives and analgesics to permit repeat neurological assessment Avoid paralytic agents if possible
Pressure area care	Loss of sensation and paralysis predisposes to early decubitus ulcers	Transfer off hardboard as early as possible Change collar to Miami J as soon as possible Roll every 2 hours Skin inspection twice a day
Hypothermia	Vasoplegia Loss of thermoregulatory control Exposure during resuscitation Pre-hospital environmental factors	External passive and active warming may be required

ISSUE	PATHOPHYSIOLOGY RELEVANT TO SCI	MANAGEMENT
Urinary retention	Paralysis of detrusor Loss of bladder sensation	Indwelling bladder catheter
Gastroparesis, increased gastric acid secretion	Loss of gastrointestinal sympathetic innervation Ileus Gastroparesis Increased gastric acid secretion	Nasogastric insertion Commence proton pump inhibitor
VTE	Immobility, Loss of peri-venous muscle pumps Endothelial damage Hypercoagulable state following trauma	Obtain lower limb Doppler USS within first week Start chemical VTE prophylaxis in <72 hours, ideally with LMWH (e.g. enoxaparin 40 mg daily)
Early surgery	Early decompression and stabilisation appear to improve neurological outcomes	Transfer to the spinal centre quickly Prioritise rapid imaging (MRI) Prioritise rapid surgery
Refer and transfer	Better outcomes in specialist spinal care centres	Early liaison and transfer to SCI specialist unit

Neurological Assessment

A thorough neurological examination should be performed as early as feasible after presentation, prior to administration of any sedative or paralytic agents. The International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) outlines a comprehensive clinical exam for patients with SCI (Fig. 81.2). The American Spinal Injury Association (ASIA) impairment scale [10] is the most validated instrument for diagnosing and classifying SCI. It is currently the only standardised neurological examination available that allows prognostication and has sufficient inter-rater reliability for local and international data collection and comparison. A bilateral sensory and motor exam, including digital rectal examination, determines a single neurological level of injury (NLI), completeness of injury and the ASIA grade (see Fig. 81.2). Table 81.2 describes the grades of the ASIA impairment scale. [10]

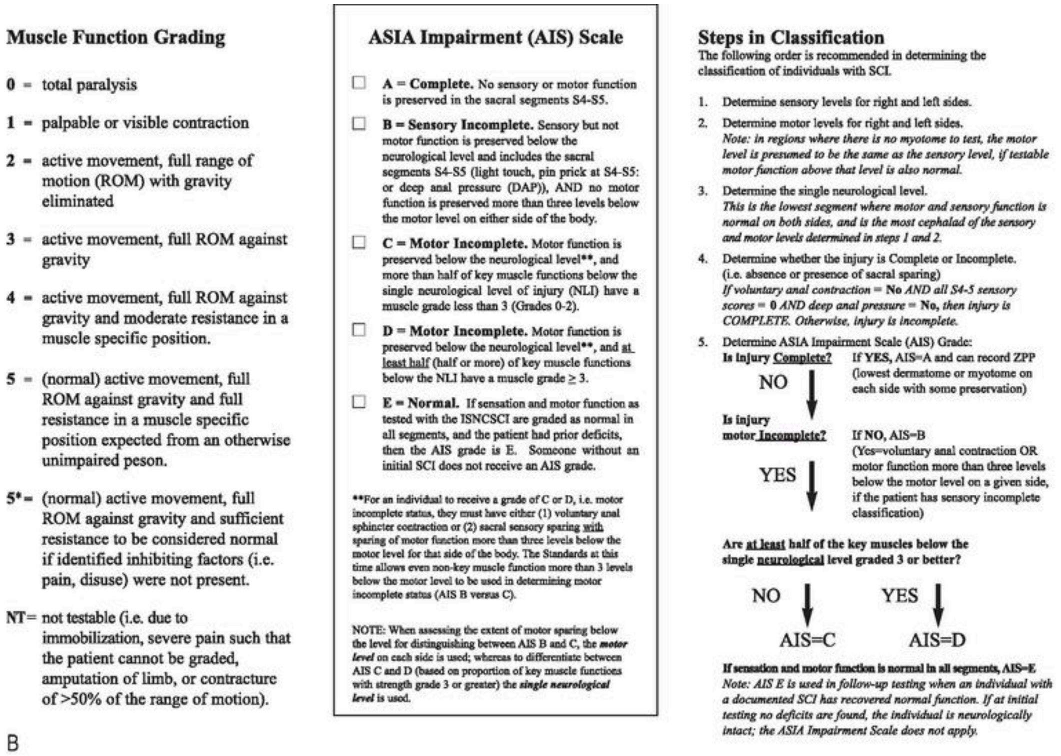
REV 04/11

A

The neurological assessment chart titled International Standards for Neurological Classification of Spinal Cord Injury by the American Spinal Injury Association and I S C o S. The left section contains boxes for documenting motor function in upper and lower limbs, listing spinal levels from C 5 to T 1 for upper limb muscles and L 2 to S 1 for lower limb muscles. Sensory scoring boxes for light touch and pin prick are listed by spinal level from C 2 to S 4 5 for both right and left sides. The right side of the chart includes front and back anatomical illustrations of a human body with labelled key sensory points across the dermatomes, from the head (C 2) to the feet (S 5). Smaller illustrations of hands and feet show palmar and dorsal surfaces with labelled dermatomes. Other sections document totals, neurological level, zone of partial preservation, A S I A impairment scale, and deep anal pressure assessment.



Muscle Function Grading

0 = total paralysis

1 = palpable or visible contraction

2 = active movement, full range of motion (ROM) with gravity eliminated

3 = active movement, full ROM against gravity

4 = active movement, full ROM against gravity and moderate resistance in a muscle specific position.

5 = (normal) active movement, full ROM against gravity and full resistance in a muscle specific position expected from an otherwise unimpaired peson.

5* = (normal) active movement, full ROM against gravity and sufficient resistance to be considered normal if identified inhibiting factors (i.e. pain, disuse) were not present.

NT= not testable (i.e. due to immobilization, severe pain such that the patient cannot be graded, amputation of limb, or contracture of >50% of the range of motion).

ASIA Impairment (AIS) Scale

☐ **A = Complete.** No sensory or motor function is preserved in the sacral segments S4-S5.

☐ **B = Sensory Incomplete.** Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5 (light touch, pin prick at S4-S5: or deep anal pressure (DAP)), AND no motor function is preserved more than three levels below the motor level on either side of the body.

☐ **C = Motor Incomplete.** Motor function is preserved below the neurological level**, and more than half of key muscle functions below the single neurological level of injury (NLI) have a muscle grade less than 3 (Grades 0-2).

☐ **D = Motor Incomplete.** Motor function is preserved below the neurological level**, and at least half (half or more) of key muscle functions below the NLI have a muscle grade ≥ 3.

☐ **E = Normal.** If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

**For an individual to receive a grade of C or D, i.e. motor incomplete status, they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than three levels below the motor level for that side of the body. The Standards at this time allows even non-key muscle function more than 3 levels below the motor level to be used in determining motor incomplete status (AIS B versus C).

NOTE: When assessing the extent of motor sparing below the level for distinguishing between AIS B and C, the ***motor level*** on each side is used; whereas to differentiate between AIS C and D (based on proportion of key muscle functions with strength grade 3 or greater) the ***single neurological level*** is used.

Steps in Classification

The following order is recommended in determining the classification of individuals with SCI.

1. Determine sensory levels for right and left sides.
2. Determine motor levels for right and left sides.
   Note: in regions where there is no myotome to test, the motor level is presumed to be the same as the sensory level, if testable motor function above that level is also normal.
3. Determine the single neurological level.
   This is the lowest segment where motor and sensory function is normal on both sides, and is the most cephalad of the sensory and motor levels determined in steps 1 and 2.
4. Determine whether the injury is Complete or Incomplete.
   (i.e. absence or presence of sacral sparing)
   If voluntary anal contraction = **No** *AND all S4-5 sensory scores =* **0** *AND deep anal pressure =* **No,** *then injury is COMPLETE. Otherwise, injury is incomplete.*
5. Determine ASIA Impairment Scale (AIS) Grade:

Is injury Complete? If **YES,** AIS=A and can record ZPP (lowest dermatome or myotome on each side with some preservation)

NO

Is injury motor Incomplete? If **NO,** AIS=B (Yes=voluntary anal contraction OR motor function more than three levels below the motor level on a given side, if the patient has sensory incomplete classification)

YES

Are at least half of the key muscles below the single neurological level graded 3 or better?

NO → AIS=C

YES → AIS=D

If sensation and motor function is normal in all segments, AIS=E

Note: AIS E is used in follow-up testing when an individual with a documented SCI has recovered normal function. If at initial testing no deficits are found, the individual is neurologically intact; the ASIA Impairment Scale does not apply.

B

FIG. 81.2 American Spinal Injury Association. International Standards for Neurological Classification of Spinal Cord Injury, revised 2011. (From Kirshblum SC, Burns SP, Biering-Sorensen F, et al. International standards for neurological classification of spinal cord injury (revised 2011). *J Spinal Cord Med* . 2011;34(6):535–546.)

Table 81.2

American Spinal Injury Association Impairment Scale

A	Complete: No sensory or motor function is preserved in the sacral segments S4-S5. Specifically no **voluntary anal contraction** and no sensation of **deep anal pressure** .
B	Sensory Incomplete: Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5
C	Motor Incomplete: Motor function is preserved below the neurological level, and less than half of key muscles below the neurological level have a muscle grade ≥3
D	Motor Incomplete: Motor function is preserved below the neurological level, and half or more of key muscles below the neurological level have a muscle grade ≥3
E	Normal: Sensory and motor function is normal and the patient with previous SCI. If initial testing after injury does not show any impairment, this classification does not apply

SCI, Spinal cord injury.

In conscious, alert patients, SCI may be obvious, with weakness, reduced sensations and absence of reflexes below the NLI, vasodilatation, priapism and urinary retention. Table 81.3 describes common pitfalls encountered with the ISCNSCI exam. An initial ASIA classification may reliably predict long-term motor outcomes. [11] However, other injuries, pain, alcohol or the administration of analgesics or other drugs may make initial assessment difficult. Signs of SCI in unconscious or uncooperative patients include:

- Response to pain above, but not below, a suspected level of injury
- Flaccid areflexia in the legs and/or arms
- Paradoxical pattern of breathing with in-drawing of the upper chest during inspiration (in the absence of upper airway obstruction or chest

injury)
- Inappropriate vasodilatation (in association with hypothermia, or in the legs but not the arms with thoracolumbar SCI)
- Unexplained bradycardia, hypotension
- Priapism
- Loss of anal tone and sensation
- No sensation of an indwelling catheter

Terminology of Spinal Cord Injury

The terminology for SCI has now been standardised by the ISNCSCI. [10]

Tetraplegia

Tetraplegia (preferred to quadriplegia) is defined as impairment of motor and/or sensory function in the cervical segments of the spinal cord due to damage to the neural elements of the spinal canal. Tetraplegia typically affects both the upper and lower limbs.

Paraplegia

Motor and/or sensory deficits affecting only lower limbs due to SCI in the thoracic, lumbar or sacral (but not cervical) segments of the spinal cord. The term is also used in referring to the cauda equina or conus medullaris injuries.

Neurological Level of Injury

The most caudal cord segment with normal sensory and anti-gravity motor function bilaterally, provided there is intact sensory and motor function rostrally (above the level). As differences often exist, it is preferred to describe the individual motor (better than anti-gravity power) and sensory levels on each side. The single NLI is then the most rostral of these levels. Note that as the spinal cord is shorter than the vertebral column, with more caudal SCI, the NLI may differ from the radiological level of injury (see Fig. 81.2).

Complete Spinal Cord Injury

SCI is complete when there is absence of both motor and sensory function in the lowest sacral segments, S4 and S5 (i.e. no voluntary anal contraction and no perianal sensation).

Zone of Partial Preservation

This term is used to describe complete (ASIA A) SCI. This refers to the spinal segments that have any motor or sensory function below the NLI.

Spinal Shock

The period of flaccid paralysis, anaesthesia, loss of bowel and bladder function and areflexia following a spinal injury is called spinal shock. It may last from 48 hours to several weeks. Emergence from spinal shock occurs gradually. During emergence, deep plantar reflex and the cutaneous reflexes (e.g. bulbocavernosus and cremasteric reflex) recover first, within 1–3 days. This is followed by the reappearance of deep tendon reflexes, usually after a few weeks. [12] Only once the spinal shock has resolved may autonomic dysreflexia (AD) manifest.

Neurogenic Shock

A form of distributive (cardiovascular) shock following SCI due to loss of sympathetic tone in peripheral vasculature.

Syndromes of Incomplete Spinal Cord Injury

Incomplete SCI may occur in the form of characteristic syndromes. [9]

Central Cord Syndrome

Central cord syndrome (CCS) is the most common type of incomplete SCI. It is characterised by motor deficit in the upper limbs which is more severe than the lower limbs, a variable sensory level below the level of the lesion, bladder dysfunction resulting in urinary retention and preserved function in the sacral segments. It was originally thought that hyperextension injury, particularly in the elderly, results in damage to more centrally located fibres of cortico-spinal tracts which provide motor control to the arms; however, recent studies have shown the cortico-spinal tracts for the upper and lower limb are more diffusely organised. The current theory is that the relative sparing of leg strength is due to the preservation of extrapyramidal fibre tracts, so central cord syndrome may not be the most appropriate name for this syndrome. [13] While traditionally the management of CCS has been expectant, recent studies have shown that early surgical decompression may improve neurological recovery. [14]

Anterior Cord Syndrome

Loss of motor function, pain and temperature sensation below the level of injury, with preservation of fine touch and proprioception. Anterior cord syndrome typically follows interruption of the blood supply to the anterior spinal cord and may be seen in patients with aortic pathology or surgery.

Posterior Cord Syndrome

Sensory ataxia or impaired voluntary movement coordination caused by a lack of proprioception. Symptoms typically worsen when a person closes their eyes. May experience sensory losses including impaired sensation of vibration and fine touch. Pain and temperature sensation preserved. Rare; usually non-traumatic causes, for example tumour.

Brown-Séquard Syndrome

Ipsilateral loss of motor, proprioception and fine touch, with contralateral loss of pain and temperature sensation below the level of injury. It usually follows a penetrating SCI damaging only one-half of the spinal cord.

Conus Medullaris Syndrome

Caused by injury at T12-L2 level causing mixed upper and lower motor neuron signs. Usually sudden, bilateral weakness in lower limbs is associated with flaccid paralysis of the external anal sphincter, faecal incontinence, bladder distension and incontinence, impotence and saddle or perianal anaesthesia.

Cauda Equina Syndrome

Results from injury to the cauda equina (usually L3-5), lead to asymmetrical, lower motor neuron lower limb weakness with sensory loss in the territory of affected nerve roots, with bladder and bowel areflexia. Caused by injuries below L1 damaging the lumbosacral nerve roots. Because of the proximity of cauda equina and conus medullaris, a single injury may affect both structures and classification of the injury to one specific syndrome may not be possible.

Associated Injuries

Overall, in major trauma, the incidence of cervical spine injury (CSI) is 1%–3%; 2%–10% of patients with head injuries have a CSI. The more severe the head injury, the more likely is CSI to be present. Patients with head injuries should be assumed to have a CSI until proven otherwise. Among patients with a cervical SCI, 25% have some degree of head injury, with 2%–3% having a severe injury. [7]

Chest injuries are often present in association with thoracolumbar injuries and are difficult to assess due to the inability to take an erect chest X-ray or the presence of a mediastinal haematoma associated with the vertebral injury. Computerised tomography (CT) of the chest may be used to assess other chest injuries, with contrast to exclude aortic injuries. There should be a high index of suspicion of abdominal injuries, as the lack of sensation, hypotension and bradycardia from the SCI may mask the usual presentation.

Immobilisation

If traumatic SCI is suspected, initial management involves manual support of the head in a natural, neutral position, limiting angular movement of the head and spine. Padding under the head (approximately 2 cm) may optimise the neutral position. [15] Semi-rigid cervical collars carry significant risks and, if used at all, should be exchanged for softer collars as soon as possible. Hard spinal boards cause rapid development of pressure injury. This risk can be minimised by transferring the patient off the hardboard as soon as feasible and providing meticulous pressure area care. Of the available hard collars, Miami J and Philadelphia collars restrict cervical movement more than Aspen or Miami J/Occian back. The Miami J and Miami J/Occian back cause the lowest levels of mandibular and occipital pressure. [16] Complications of prolonged immobilisation and spinal precautions include cutaneous pressure ulceration, difficult intubation, potential venous obstruction leading to high intracranial pressure, reduced options for central venous access, higher risk of venous thromboembolism (VTE), increased risk of respiratory infections due to restricted physiotherapy, gastroparesis and an inability to provide optimal oral care. [17]

Imaging

Is Imaging Required?

Some trauma patients may not require cervical spinal imaging and the inherent risks that this entails. Two clinical decision tools are used in this context: The National Emergency X-Radiography Utilisation Study (NEXUS) criteria and the Canadian C-Spine rule (CCCR). NEXUS suggests cervical spine imaging is indicated for patients with trauma unless they meet all of the following criteria [18] :

- No posterior midline cervical spine tenderness
- No evidence of intoxication
- Normal level of alertness
- No focal neurological deficit
- No painful distracting injuries

NEXUS criteria have a very high sensitivity (99.6% for significant injuries) if used as initially intended, although the specificity is only 12.9%. They require there to be no evidence of any intoxication (including even an odour of alcohol), an alert level of consciousness is sufficient to allow *three object recall at five minutes* , no focal neurological deficits and there should be no painful distracting injuries. This subjective component includes any long-bone fractures, de-gloving injuries, deep lacerations, visceral injuries, crush injuries, large burns or any injury that causes any acute functional impairment. The Canadian C-Spine rules have a higher degree of sensitivity (100%) and specificity (45%) but were based on a smaller cohort of patients than NEXUS. [18] Again, they only define which patients may be clinically cleared without imaging.

Imaging Modalities

Plain Radiographs

Adequate, three-view combination (A-P, lateral and odontoid peg view) plain radiography misses injuries of the spinal column in both alert and obtunded patients, with a pooled sensitivity of detecting significant injuries of 52%. [19] Despite reducing thyroid radiation exposure in comparison to CT, plain radiography has no role in this context, unless other modalities are not available.[20]

Dynamic Studies (Dynamic Fluoroscopy or Flexion/Extension Radiography)

This imaging modality poorly visualises the relevant anatomy[21] and has a low sensitivity to detect injury.[22] It is labour and resource intensive,[23] may worsen injury and has been superseded by CT and magnetic resonance imaging (MRI).

Computerised Tomography

64 slice, multidetector row CT (MDCT) offers high sensitivity in detecting spinal injuries, including ligamentous injury. If a patient has no gross neurological deficit and the CT is interpreted by an experienced radiologist, MDCT has a detection rate of nearly 100%.[24] Disadvantages include significant thyroid radiation exposure and the transport of a trauma patient to CT.[17]

Magnetic Resonance Imaging

To investigate cord injury, MRI provides superior imaging to any other modality.[25] MRI provides a detailed image of the spinal cord, spinal ligaments, intervertebral discs and paravertebral soft tissues. It is the most sensitive screening test available to detect soft tissue and ligamentous injuries that could contribute to instability of the cervical spine[26] and MR angiography may detect associated vertebral artery injury. In the setting of trauma, MRI imaging supplements the information obtained from a CT scan and does not replace the need for a CT.

Timing of MRI is a contentious issue, as with time, the MR signal may change due to a decrease in ligamentous oedema. The Eastern Association for the Surgery of Trauma guidelines recommend that MRI should be performed within 72 hours[27] ; however, there is only limited evidence that delay between injury and imaging results in a false negative MRI.[28]

An Approach to Imaging

There is currently no universal consensus on spinal imaging post trauma. If there is no neurological deficit but the other conditions of the Canadian C-Spine Rule or NEXUS rules are not met, then high-resolution MDCT of the spine is indicated. If there is evidence of any new neurological deficit attributable to an SCI, an urgent MRI should be performed. If an obtunded, blunt-trauma patient is able to move all four limbs, and an MDCT has been reported to show no injury by a consultant neuroradiologist, the C-spine may be cleared without an MRI. [29] If an obtunded, blunt-trauma patient with a mechanism compatible with SCI is unassessable, and anticipated to remain so for >72 hours, an MRI can follow the MDCT.

Policy for the use of MRI in this context should be discussed at an institutional level, with the knowledge that MDCT alone may miss a small percentage of injuries that would otherwise have required intervention, but the false-positive rate of MRI may result in significant morbidity to patients with no injuries who are kept immobilised. [17]

If a cervical fracture is identified, a CT or MR angiogram should be performed to assess for vertebral artery injury. The risk of vertebral artery injury is especially high in patients with CSCI associated with fracture extending to the transverse foramen, basilar skull fracture, facet joint subluxation/dislocation or co-existing disease such as diffuse idiopathic skeletal hyperostosis or ankylosing spondylosis. [30]

Intensive Care Management of Spinal Cord Injury

Prevention of Secondary Neurological Injury After Spinal Cord Injury

Spinal cord compression may occur due to misalignment of the spine, oedema or haemorrhage. Incomplete injury with spinal cord compression should be urgently decompressed. Stability is the ability of the spine, under physiological loads, to limit patterns of displacement, which would result in neurological injury, pain or deformity. [31] It is affected by fracture morphology and osteo-ligamentous integrity. Most unstable spinal injuries require operative intervention. Where indicated, early surgery within 24 hours of injury is safe, may improve neurological outcome, reduces length of stay in acute care, permits early mobilisation and commencement of deep vein thrombosis prophylaxis and lowers hospital cost. [32] Most spinal surgeons prefer to operate as early as possible in patients with incomplete or cervical SCI.

Many pharmacological agents have been investigated for preventing secondary injury and aid the recovery of damaged neurons; however, none of these have proven successful. NASCIS 2 [33] and NASCIS 3 [34] were the largest trials that investigated the role of corticosteroids after SCI. Both were negative studies, showing no significant difference in motor scores between treatment groups at any time. Post-hoc, sub-group analysis of these data that suggested improvement in neurological outcome was fundamentally flawed. The lack of evidence for efficacy, and significant adverse effects such as detrimental effects on concomitant head injury, has resulted in a decline in steroid use in recent years. Other agents that have been investigated with no evidence of benefit include GM-1 ganglioside, tirilazad, naloxone and nimodipine.

Induced hypothermia has been reported to be beneficial in case reports, but there is not enough evidence to recommend this intervention. [35] Fever may worsen the outcome and normothermia should be maintained.

Patients typically spend several weeks to months in the hospital. Early referral to a rehabilitation team specialising in the management of SCI should be made so that acute management and rehabilitation may proceed hand in hand.

Respiratory Dysfunction

Respiratory dysfunction is a major cause of morbidity after SCI, especially after cervical SCI. Diaphragm, external intercostals, scalene and sternocleidomastoid are the key muscles of inspiration. Quiet expiration is passive, but forceful expiration and cough require abdominal muscles, interosseous part of internal intercostals, latissimus dorsi, serratus posterior and inferior, triangularis sterni and quadratus lumborum. The effect of SCI on respiratory function depends upon the NLI. Various effects of cervical SCI on respiratory function are listed in Table 81.4 . The diaphragm is innervated by C3–C5. If the NLI is above C5, sternocleidomastoid (innervated by cranial nerve XI and anterior rami of C2, C3), and scalene medius and posterior (innervated by C3–C4) become important muscles for inspiration. The abdominal muscles are innervated by T7-L1, and in higher injuries, cough is generated only by the muscles of the upper chest, particularly the pectoralis major. [36]

Table 81.4

Effect of cervical spinal cord injury on respiratory function

Decreased vital capacity	Paralysis of diaphragm and intercostal muscles Distortion of rib cage in inspiration due to paralysed intercostal muscles
Reduced compliance of lungs and chest wall	Spasticity of intercostal muscles Altered articulation of ribs to sternum and vertebrae Low functional residual capacity Atelectasis Possible alteration of surfactant
Increased abdominal compliance	Paralysis of abdominal muscles
Increased bronchial tone and secretions	Sympathetic denervation
Poor cough	Reduced vital capacity Abdominal muscle paralysis
Sleep-disordered breathing (develops within 6 months)	Unknown cause Increased adipose tissue around the neck Antispasticity drugs

Respiratory Management After Cervical Spinal Cord Injury

Intubation may be required for respiratory failure, secretion clearance, surgery, decreased level of consciousness or because of other injuries. Almost 75% of patients with cervical SCI will require intubation and mechanical ventilation. [37]

Airway Management after Spinal Cord Injury

At the time of intubation, a trauma victim may have proven or suspected cervical SCI. Both flexion and extension of the cervical spine may reduce the cross-sectional area of the spinal canal, and therefore cause spinal cord compression. A cervical hard collar reduces mouth opening, which makes direct laryngoscopy difficult. In a study on patients with no CSI, all of whom had laryngoscopy Grade I or II view, application of hard neck collar, forehead tape and sandbags resulted in change of laryngoscopy grade to III or IV in 64%. [38] Even manual in-line stabilisation reduces the grade of laryngoscopy view in 45% of patients. [39] Small studies have shown that video laryngoscopy is associated with less movement at atlanto-occipital joint and atlanto-axial joint. [40] When intubating a patient with suspected or proven cervical SCI, a senior clinician should be involved. Video laryngoscopy provides an improved view in the setting of spinal immobilisation, facilitates less movement of the cervical spine and is considered the standard of care. [41] Denervation results in the rapid proliferation of extra-junctional acetylcholine receptors. Use of succinylcholine should be avoided for intubation after 48 hours of injury as it may result in dangerous hyperkalaemia. In patients with cervical SCI, bradycardia is common during intubation. [42] The use of anticholinergic agents such as glycopyrrolate or atropine may achieve the dual purpose of reducing salivary and airway secretions, and prevent bradycardia.

Mechanical Ventilation

In the initial period after cervical SCI, ventilator settings are dictated by associated injuries, for example traumatic brain injury, lung contusion, etc. Once acute issues have been resolved, mechanical ventilation should be tailored to SCI.

Tidal volume (V_T) of more than 10 mL/kg is often used in patients with cervical SCI. The rationale for high V_T ventilation is to prevent atelectasis and reduce the sensation of ‘air hunger’ experienced following SCI. This avoids the need for high-level positive end-expiratory pressure (PEEP) that may lower the position of the diaphragm to one of mechanical disadvantage. In some spinal centres, V_T of 10–20 mL/kg is used routinely, [43] and in small studies has not resulted in a higher incidence of ventilator-induced lung injury. [44] With high V_T , dead space may have to be incorporated into the circuit to avoid hypocapnia. Another approach is to use more conventional V_T and higher PEEP to prevent atelectasis. Until better quality evidence is available, an individualised approach to ventilator settings should be used.

Atelectasis may result in respiratory failure. For patients with tracheostomy in whom the cuff is deflated, leaks during positive pressure should be accounted for in the ventilator settings. Most literature on mechanical ventilation in SCI comes from long-term ventilation units. Further research on mechanical ventilation in the subacute phase, while still in the intensive care unit (ICU), for patients with cervical SCI is needed.

Extubation after mechanical ventilation in patients with cervical SCI requires careful consideration of several factors (Table 81.5), with failure likely to result in re-intubation followed by tracheostomy. Extubation failure is commonly due to retained secretions, inadequate cough and sputum plugs. Patients may benefit from extubation to non-invasive ventilation directly, which may be required for several days. A variety of non-invasive ventilation interface devices should be available and nasal skin should be protected from developing pressure ulcers. Frequent chest physiotherapy and assisted coughing using a ‘cough assist device’ are often required to clear secretions.

Table 81.5

Checklist prior to extubation

1.	No further procedure or imaging outside the ICU anticipated in next 24 h
2.	No significant hypoxia or reversible respiratory pathology
3.	Ability to tolerate non-invasive ventilation
4.	No contraindication for the assist cough or chest physiotherapy (e.g. rib fractures and major laparotomy)
5.	Minimal respiratory secretions
6.	Negative inspiratory force >20 cm H_2O
7.	Vital capacity >10 mL/kg
8.	Presence of cuff leak (particularly after spinal fixation by anterior approach)
9.	Airway plan and equipment ready for re-intubation

ICU , Intensive care unit.

The tracheostomy rate after cervical SCI varies between 20% and 60%. Complete injuries above C5 usually require tracheostomy. [45] A high NLI, complete SCI, associated facial fractures, thoracic trauma and emergency intubation are associated with the need for tracheostomy. Percutaneous tracheostomy is as safe as surgical tracheostomy and offers advantages. [46] Early tracheostomy may reduce the duration of mechanical ventilation and ICU length of stay and it does not increase the risk of wound or implant infection even after anterior spinal fixation. [47]

Weaning from mechanical ventilation after cervical SCI may take considerable time. In some centres, high-level tetraplegic patients are cared for in chronic respiratory care facilities rather than the ICU. It is important that a long-term weaning strategy is agreed upon and adhered to by all members of the multidisciplinary team. Accurate neurological assessment, progressive ventilator-free breathing, adequate rest periods with controlled ventilation and secretion control with aggressive physiotherapy are associated with successful weaning. [48] Preventing fatigue during weaning is important, and time off ventilator should be gradually increased, often starting with much briefer periods than for patients with other aetiologies of respiratory failure. It is important to acknowledge that patients with SCI may take much longer to wean than other ICU patients. Inspiratory muscle training uses an inspiratory resistor to increase the strength of inspiratory muscles. While more studies are needed to clearly delineate the role of inspiratory muscle training in weaning patients with cervical SCI, its use makes physiological sense and is being used increasingly. [49] It should be remembered that most patients with cervical SCI ventilate more easily when supine compared to being upright, as their abdominal contents can push the diaphragm up into a position of better mechanical advantage in the supine position. An abdominal binder may be used in the sitting position, which also helps in this regard.

Inhaled anticholinergics and beta-2 agonists reduce airway resistance but have not been shown to improve the success of weaning. Anabolic steroids like oxandrolone do not improve respiratory function but may cause hepatotoxicity and dyslipidaemia. Phrenic nerve or direct diaphragmatic pacing systems are occasionally used for respiratory support in high-level tetraplegics.

The NLI is the strongest predictor of successful weaning. [50] Patients with complete injuries at or above C3 are likely to need permanent ventilation. Early identification of patients who cannot be weaned helps reduce their ICU length of stay and expedites the arrangements for equipment and care personnel required for home ventilation or transfer to a chronic respiratory care facility. Overall, approximately 2% of patients with SCI, mostly with complete injuries at C1–C4, require life-long ventilation. [51]

Cardiovascular Dysfunction After Spinal Cord Injury

The heart receives its sympathetic innervation from the upper thoracic segments via the superior, middle and inferior cervical ganglions. Vasomotor tone of the peripheral vasculature is also controlled by segmental sympathetic innervation. The heart’s parasympathetic innervation comes from the vagus and therefore is not affected by SCI. Following SCI, loss of sympathetic supply and unopposed vagal activity may cause profound vasoplegia combined with bradycardia, resulting in hypotension and neurogenic shock. This occurs in 19% of patients with cervical and 7% of patients with thoracic SCI. [52] Other causes of hypotension, particularly hypovolaemic shock, must be excluded before a diagnosis of neurogenic shock is made. Bradycardia and even asystole may occur during routine ICU procedures such as endotracheal suction or repositioning in bed after cervical SCI. This occurs most commonly in the first week and generally resolves within 2–6 weeks after injury. [53]

There is some low-quality evidence that maintaining a higher mean arterial pressure (MAP) following SCI may improve cord perfusion pressure, prevent secondary injury and improve neurological outcomes. Much is still unknown about this aspect of treatment, including the ideal MAP to target, optimal duration of blood pressure augmentation, the best vasopressor to use and whether the injury being complete or not is significant. Ongoing trials seek to answer some of these questions. Current guidelines recommend systolic blood pressure should not be less than 90 mm Hg at any time and that an average MAP above 85–90 mm Hg be maintained for 7 days following injury. [54] Whether the use of a lumbar CSF drain improves spinal cord perfusion, with or without MAP augmentation, also remains to be determined.

Cardiovascular Complications

Autonomic Dysreflexia

AD is a medical emergency characterised by acute hypertension due to severe sympathetic stimulation in patients with injuries above T6. It occurs following the resolution of spinal shock and is a frequent cause of admission to the ICU. AD occurs due to dysregulated sympathetic activation leading to intense vasoconstriction below the level of lesion. Compensatory parasympathetic activation leads to bradycardia, vasodilatation and sweating above the NLI. [55] Other symptoms include headache, blurred vision, nausea and nasal congestion. The precipitants, investigations and treatment of precipitating factors are outlined in Table 81.6 .

Table 81.6

Precipitants, investigations and treatment of autonomic dysreflexia

PRECIPITANT	INVESTIGATION AND TREATMENT
Bladder distension (caused in 75%–85%)	Insert or change bladder catheter
Faecal impaction (cause in 13%–19%)	Digital examination Laxatives Enema Manual dis-impaction
Urinary tract calculi	CT scan of urinary tract Cystoscopy or surgery to remove calculi
Urinary tract infection	Urinary microscopy and culture Appropriate antibiotics
Haemorrhoids or anal fissure	Laxatives Dietary management
Decubitus ulcers, with or without infection	Rule out underlying osteomyelitis Pressure area care Consider plastic surgery Consider antibiotics
Foot disease including ingrown toenails	Nail care
Procedures (e.g. suprapubic catheter insertion, cystoscopy and urodynamic studies)	Spinal anaesthesia may prevent AD
Heterotopic ossification	Bone scintigraphy

PRECIPITANT	INVESTIGATION AND TREATMENT
	Measure C reactive protein and creatine kinase Physiotherapy Surgery
Pelvic stimulation (sexual activity, menstruation, labour)	Education Be prepared in peripartum period
Skeletal fractures	High index of suspicion below NLI

AD, Autonomic dysreflexia; *CT,* computerised tomography; *NLI,* neurological level of injury.

From Blackmer J. Rehabilitation medicine: 1. Autonomic dysreflexia. *CMAJ* . 2003;169(9):931–935.

Initial management includes primarily detecting and treating the precipitant, sitting the patient up (to induce an orthostatic hypotensive response), loosening tight clothing and anti-hypertensives. Sublingual or transdermal glyceryl trinitrate is used initially. Nitrates should be avoided in patients who have taken sildenafil for erectile dysfunction in the preceding 24 hours due to the risk of severe and protracted hypotension. [56] Sublingual captopril or oral prazosin may be used in unresponsive patients before intravenous agents such as sodium nitroprusside or glyceryl trinitrate infusions are used. Invasive blood pressure monitoring is required if intravenous agents are used. Some patients may develop chronic, severe AD requiring multiple anti-hypertensives. It must be remembered that in the setting of chronic hypotension that may follow SCI, systolic blood pressure of even >150 mm Hg may be life threatening, [57] and cause intracerebral haemorrhage or myocardial ischaemia.

Venous Thromboembolism (VTE)

The combination of immobility, loss of peri-venous muscle pumps, endothelial damage and the hypercoagulable state following trauma, make VTE following

SCI common; the incidence is up to 100%.[58] With prophylaxis, this incidence is reduced, but ~5% of patients with SCI will still develop VTE,[59] and pulmonary embolism remains a leading cause of death. VTE is more common in complete SCI and in high thoracic SCI patients than cervical or low thoracic/lumbar SCI REF.

The risk of VTE increases significantly after 72 hours of injury,[60] therefore ideally any surgical procedures should occur early to allow commencement of chemical VTE prophylaxis. Low-molecular-weight heparin (LMWH) (e.g. enoxaparin 40 mg daily) is the recommended thromboprophylaxis after SCI,[61] probably being more effective than low-dose unfractionated heparin (e.g. 5000 units, twice daily),[61] with less bleeding complications.[62] Direct oral anticoagulants may be even more efficacious than LMWH,[63] but this is not current standard practice. Evidence for duration of prophylaxis is lacking but it is often used for 3 months, taking individual patient factors into consideration.[62] If pharmacological VTE prophylaxis is contraindicated, a retrievable inferior vena cava filter may be considered, though evidence for their efficacy post SCI is lacking.[64]

Gastrointestinal Complications

Paralytic ileus and acute gastric dilatation are common in the first few days following SCI. Unopposed parasympathetic activity results in stomach hyperacidity, necessitating a proton pump inhibitor for ulcer prophylaxis in the early days after the injury.

The upper motor neuron bowel syndrome seen in lesions above the T10 is characterised by increased colonic transit time, increased anal sphincter tone and impaired sensation of fullness of the rectum, which results in constipation and faecal retention.

Stool softeners (e.g. coloxyl) are generally required. Stimulants (e.g. Senna) may be used at nighttime. Rectal stimulation is often necessary and may be achieved by glycerine suppository, enema or digital stimulation. (The so-called 3-2-1 regimen employs three times a day coloxyl; two tablets of Senna at nighttime; and rectal stimulation once before the planned time of defaecation.) In patients who can eat, bowel motions should be planned after breakfast, taking advantage of the gastrocolic reflex. Other components of bowel management programmes include adequate fluid intake, adequate dietary fibre, abdominal massage and, rarely, surgery (e.g. colostomy) or electrical stimulation. Opioids and other constipating medications should be avoided where possible. [65]

In lower motor neuron bowel syndrome, seen in cauda equina injuries, the external anal sphincter is lax but colonic peristalsis is inhibited, leading to both constipation and overflow incontinence. These patients benefit from increasing stool bulk (with fibre) and usually require manual evacuation.

Urinary Tract Complications

Most patients with an NLI above L1 experience detrusor overactivity with sphincter dyssynergia. This results from the upper motor neuron lesion causing overactivity of both detrusor and the bladder sphincter. As a result, the detrusor contracts against the closed sphincter, leading to high intravesical pressure, vesicoureteral reflux, high residual volume, incontinence, bladder spasm and an increased risk of urinary tract infections. Most patients with complete cervical SCI will require a suprapubic cystostomy, while thoracolumbar injuries may be managed by intermittent self-catheterisation. Detrusor overactivity, leading to bladder spasms, is common. Anticholinergics such as oxybutynin (oral or transdermal), tolterodine or solifenacin are used for treatment. In severe cases, intra-detrusor botulinum toxin injection may be required. The anticholinergic side effects of these agents may be significant. Most patients require a combination of two anticholinergic medications.

Following SCI, there is a marked alteration in calcium homeostasis, with potential hypercalcaemia, hypercalciuria and a significant risk of calcium oxalate nephrolithiasis.

Musculoskeletal Complications

Muscle spasticity is a common but late complication. It develops after resolution of spinal shock and is characterised by increased muscle tone, hyperreflexia and muscle spasms below the NLI. Nociceptive stimuli below the level of injury (e.g. constipation and urinary tract infection) should be ruled out in patients with spasms. The initial treatment is oral baclofen. Its side effects include sedation, fatigue and confusion that may interfere with weaning from mechanical ventilation or participation in rehabilitation programme. Intrathecal baclofen, local botulinum toxin, gabapentin, pregabalin and benzodiazepines are also used for severe spasticity. [57] Physiotherapy is needed to preserve a full range of movement and prevent contractures.

Skin Care

Pressure ulcers are common due to immobility and lack of sensation. Nearly 30% of patients with SCI develop pressure ulcers during their hospital stay, and half of these occur within the first month. [66] They are a source of significant morbidity and are associated with increased hospital length of stay, life-threatening infections, chronic osteomyelitis and AD. Skin healing in denervated skin is significantly delayed, so prevention is vital. The incidence of pressure areas may be reduced by:

- Twice daily skin inspection to detect early pressure areas
- Scheduled, frequent patient repositioning
- Good bowel and bladder care
- Pressure relieving mattress
- Prevention of accumulation of moisture
- Optimal nutrition
- Patient participation in their skin care programme

Psychosocial Support

Prolonged supportive care is necessary for both patients and their families to help them accept and adapt to neurological disability. Depression is common after SCI. Major depression should be differentiated from depressed mood. Healthcare workers may have the tendency to overdiagnose depression and conversely, depressive symptoms may be misinterpreted as somatic symptoms (e.g. fatigue). Since many patients require antidepressants for pain and are also on drugs with anticholinergic effects (e.g. tolterodine and oxybutynin), management of depression is complex and specialist psychiatric consultation should be sought.

Chronic Pain

Chronic pain is a frequent complication after SCI that occurs in up to two-thirds of patients. Pain after SCI may be classified as nociceptive pain from stimulation of nociceptors, or neuropathic pain from damage to the sensory system itself. Most patients will report the onset of chronic pain within 6 months after the injury, and frequently while still in the ICU. Gabapentinoids (gabapentin and pregabalin) for neuropathic pain have the strongest evidence to support their efficacy. [67] Tricyclic antidepressants such as amitriptyline are effective for neuropathic pain in patients who also have depression. Infusions of opiates, ketamine and lignocaine are effective for neuropathic pain in the short term. [67] Cognitive behavioural therapy may be useful in addition to pharmacological treatment. Consultation with a pain specialist should be sought in patients with severe, refractory pain.

Readmission to the Intensive Care Unit

Common causes for readmission to the ICU for patients with pre-existing SCI are infections (urinary tract infections, pneumonia), AD, VTE and surgery (commonly after urinary tract procedure for renal stones). Meticulous attention should be given to skin care. All usual medications should be continued if possible. Abrupt withdrawal of baclofen may lower the seizure threshold. Risk of venous thromboembolism may be higher, and thromboprophylaxis should be used as appropriate for the clinical condition. The use of succinylcholine for intubation may precipitate severe hyperkalaemia.

Outcomes Following Spinal Cord Injury

Hospital survival after SCI is now more than 90%, with long-term survival substantially better than it was 40 years ago. [68] Factors predictive of higher mortality include higher NLI, complete SCI, older age and presence of co-morbidities. [69] Depending on the individual circumstances, it may be appropriate to have limitations of treatment for elderly patients with complete and high NLI. Most deaths are due to respiratory and cardiovascular disease.

The neurological outcome post SCI is best prognosticated with an accurate neurological assessment using the ISNCSCI exam. Even during the first 24 hours, a reliable exam is highly predictive of outcome; however, neurological improvement continues up to 18 months (sometimes longer), with the majority of that improvement occurring in the first 3 months.

Complete (ASIA A) injuries have the least potential for recovery, with only 20% converting to ASIA B by 1 year and none becoming motor incomplete.

However, 74% of ASIA B patients convert to ASIA C or D by 1 year with much better functional outcomes, and nearly all ASIA C under 50 years of age and all ASIA D patients are expected to be ambulatory on discharge from rehabilitation. [68]

In the absence of a clinical exam, imaging may be used to prognosticate (see Table 81.7), but is less reliable than clinical exam.

Table 81.7

Imaging features predictive of worse neurological injury [74]

MODALITY	IMAGING FEATURE/SCORE	EXPLANATION
MRI T2 sequences	Sagittal grade/length score	Longer abnormal T2 signal worse Presence of haemorrhage worse
	Maximum canal compromise score	The percentage of spinal canal affected – more is worse
	Maximum spinal cord compression score	The degree to which the cord is compressed – more is worse
	Axial grading (BASIC) score	Worse if white matter as well as grey affected Worse if haemorrhage present
CT	Presence of facet dislocation	‘Locked’ facets give worse prognosis

Despite significant disability, practical function may be surprising to those who only manage the acute phase of SCI. For example someone with a C5 ASIA A SCI may be able to mobilise with a power wheelchair with hand controls, drive a modified vehicle, have a family and a rewarding career.

The treatment offered to the patient may be influenced by the physician’s understanding of the outcome, quality and satisfaction with life after SCI. Physicians may imagine the quality of life following SCI to be more negative than it actually is. [70] It is vital that critical management decisions, particularly those related to treatment limitation, are not made in haste.

Future Directions

There is growing evidence that early surgery (e.g. <8 hours from injury) may improve neurological outcomes. [71] Optimal blood pressure targets and the benefits of spinal drains and perfusion pressure targets remain unknown. Current pharmacological research is focusing on neuroregenerative agents, such as Rho-rock inhibitors and anti-NOGO monoclonal antibodies, as well as neuroprotective agents such as riluzole. [72] There is much ongoing interest in cell-based regenerative strategies, for example endogenous stem cells with or without bioresorbable scaffolds. [72]

Other avenues include epidural electrical stimulation and brain-computer interfaces. [73] Time will tell what becomes clinically relevant.

Abdominal and pelvic injuries

Sarah McNeilly

Almost 25% of major trauma admissions suffer injury to the abdomen or pelvic contents with solid organ injury most common.[1,2] Mortality from pelvic injury is nearly 10%, whereas abdominal injuries carry a mortality of 8%.[3,4] Haemorrhage is the most common cause of preventable trauma death.[5-7] Injuries can be divided into blunt or penetrating, with most abdominal and pelvic injuries being caused by blunt trauma. Penetrating aetiologies can account for up to half of cases, depending on the society concerned with a rising incidence in Europe.[8] Conversely, incidence is declining in the USA.[9]

Mechanisms of Injury

Blunt Injuries

Road traffic collisions (RTCs) are the most common cause of blunt trauma to the abdomen and pelvis.[10] Other common causes include falls, assaults, sporting accidents and industrial accidents. Associated injuries are frequent, involving the thorax, head and extremities. As the trauma population gets older, the incidence of significant trauma from a low mechanism of injury (for example fall from standing) is increasing.[2] Seat belts and airbags considerably reduce mortality in RTCs, but airbags can be associated with thoracic injuries, including occult injuries to the great vessels and heart, particularly in decelerating incidents with an unstrained passenger.[11,12]

Penetrating Injuries

Stab and gunshot wounds account for most penetrating injuries to the abdomen.

Stab and Laceration Wounds

Neither entry site(s) nor implement used accurately predicts the nature of deeper injury. With penetrating injury in the thoraco-abdominal area, damage to both thoracic and abdominal organs should be suspected, including damage to the diaphragm. Laparotomy remains the treatment of choice for patients with haemodynamic compromise, evisceration or impalement. Treatment of the stable patient is either laparoscopic exploration or a conservative approach may be appropriate in some patients. This avoids the morbidity associated with laparotomy with no reduction in safety. [13 - 16]

Gunshot Wounds (See also Chapter 105 : Blast and Ballistic Trauma)

Injuries depend on missile calibre, its velocity and trajectory. Both injuries and mortality are substantially greater than with stab wounds. Laparotomy should be performed in all cases with haemodynamic instability, signs of peritonism and associated injuries (or intoxication) that prevent serial abdominal examinations or confirmed rectal, bladder or ureter injuries. A non-operative approach for selected low-risk patients has been shown to be safe but is not yet universally accepted. [17]

Initial Treatment and Investigations

Resuscitation

Initial assessment and resuscitation of the patient are performed simultaneously. The traditional ABC (airway, breathing, circulation) order of assessment and resuscitation has been replaced by <C>ABC, where <C> stands for ‘catastrophic haemorrhage’. [18] This concept originated on the battlefield where there was high mortality from external peripheral haemorrhage. Essentially, any massive haemorrhage is controlled with compression, tourniquet, haemostatic dressing or splintage before airway and breathing are addressed.

The aim of damage control resuscitation (DCR) is to provide haemostasis, with permissive hypotension to decrease bleeding and regain homeostasis in patients with life-threatening haemorrhage. Resuscitation with blood and blood products and the avoidance of crystalloids aim to treat and control coagulopathy early in the process and have been shown to improve survival. [19 - 21] (See haemorrhage and coagulopathy section.)

Clinical Assessment and Initial Investigations

An initial primary survey is performed with the aim of identifying major life-threatening injuries requiring immediate attention. Mechanisms of injury can give important information in terms of likely injury patterns. In crush injuries, abdominal organs are crushed between the abdominal wall and spine or ribs; sudden extreme external compression may also cause the rupture of the hollow viscera. Rapid deceleration causes shearing forces which means adjacent structures move in opposite directions, tearing at points of fixation such as vascular pedicles and mesenteric attachments. [22]

Physical signs and symptoms of internal injury in the abdomen are often unreliable, especially if the patient has other injuries (particularly head) or is intoxicated. [4]

Pelvic injuries can be difficult to detect by clinical examination alone. Patients may present with a pelvic binder in situ having been applied in the pre-hospital phase and this should not be removed for examination. If no binder is in situ, but pelvic injury is suspected, then one should be applied as part of the primary survey. The pelvis should not be ‘sprung’ to look for instability, as this may disrupt clots and cause further haemorrhage. [23] A log-roll should be avoided if there is suspicion of pelvic fracture.

Pain around the pelvic area or lower back, asymmetry of the lower limbs or pelvis, or bruising around the perineum and scrotum can all be indicative of a pelvic fracture. Blood at the urethral meatus or haematuria are indications that there are associated urethral or bladder injuries.

Initial investigations should occur simultaneously with the primary survey. Blood samples should be sent for full blood count, clotting studies, renal and liver function and group and screen with cross-match if bleeding is suspected. Venous blood gas analysis should also be performed to assess for acidaemia and to measure the lactate level. Thromboelastography (TEG) or rotational thromboelastometry (ROTEM) provides rapid information on deficiencies in clotting factors, clot strength and clot breakdown, which helps to guide transfusion.[24]

Choice of Investigations

The aim of the initial assessment and investigations of a patient with major trauma should be to rapidly identify and treat life-threatening injuries. The choice of diagnostic investigations should streamline this process. In patients with major haemorrhage, immediate computed tomography (CT) should be considered if they are responding to resuscitation or haemodynamically normal. Other diagnostic imaging (plain X-rays or focused assessment with sonography for trauma [FAST]) should be the minimum needed to direct interventions in those too unstable for a CT scan.[25]

Plain X-Rays

Portable plain anteroposterior (AP) X-rays of the chest and pelvis are often performed during the primary survey to exclude life-threatening tension pneumothorax and unstable pelvis fracture, though these may be excluded if the patient is going for immediate CT scan and should not delay this process.[22], [25] Plain AP X-ray of the pelvis may appear normal, even with the presence of an unstable pelvic fracture, if there is a well-fitting pelvic binder in situ.

Computed Tomography

In the polytrauma patient, the CT scan is the imaging of choice to identify the patient’s injuries, though this may not occur until after emergency haemostatic interventions such as laparotomy or angioembolisation. Current guidelines from the National Institute for Health and Care Excellence (NICE) recommend a whole-body CT (from vertex to toe on the scanogram and vertex to mid-thigh for the CT scan) in the blunt polytrauma patient. [25]

A single bolus of intravenous contrast agent is used and the use of a multidetector scanner allows the capture of arterial and portal venous phases and a delayed phase if necessary. The arterial phase will demonstrate vascular injury or ongoing arterial bleeding from, for example, a displaced pelvic fracture.

With isolated gunshot wounds to the abdomen in stable patients, a CT scan can aid the decision for conservative management, as the bullet trajectory is shown alongside any organ damage caused. [9] As the quality of CT scans has improved over time with improved technology, their use in stabbings has increased significantly. [26]

Ultrasonography

The FAST has become an important part of the primary survey of unstable trauma patients in the resuscitation room. [4] The bedside assessment of the heart, pericardium and abdomen allows the rapid detection of life-threatening conditions, expediting their immediate treatment. More recently, the extended-FAST (E-FAST) has taken over, which includes assessment for pneumothoraces. Ultrasound has shown to be more specific and sensitive for pneumothorax than the plain chest X-ray. [27]

In the stable trauma patient, E-FAST combined with clinical examination has been shown to be adequate in ruling out life-threatening injuries before a CT scan, meaning routine plain imaging of the chest and pelvis is unnecessary. [27] In the very early post-injury phase, false negatives may be found when looking for fluid in the peritoneum. [28] It is also poor at identifying retroperitoneal fluid and intra-abdominal organ injury without bleeding. Like most imaging, E-FAST is operator dependent.

Peritoneal Lavage

The use of E-FAST and rapid CT scanning has meant that diagnostic peritoneal lavage (DPL) is now rarely indicated.[4] It may still be used in a resource-poor environment if there is no access to either ultrasound or CT scanning.[26]

Laparoscopy

The role and evidence for laparoscopy have increased significantly in recent times for both blunt and penetrating trauma.[14,29,30] In penetrating trauma it is useful in evaluating haemodynamically stable patients and significantly reduces the rate of non-therapeutic laparotomy which has considerable morbidity attached to it.[13,29] In blunt trauma, it is used for both diagnostic and therapeutic reasons in stable patients and bridges a gap between conservative management and laparotomy.[30]

Management of the Unstable Patient

In patients with abdominal or pelvic trauma with haemorrhage, rapid transfer to either theatres or the angiography suite for either a laparotomy or angiography is required. These procedures are both diagnostic and part of the definitive treatment of the patient. Resuscitation should continue throughout this time.

Interventional Radiology

Angioembolisation is now a widely accepted treatment option for patients with solid organ injury and evidence of active contrast extravasation on CT scan.[31] It is also now the standard of care for patients with retroperitoneal arterial bleeding from pelvic fractures.[32] It allows rapid haemorrhage control in an area which is difficult to access surgically whilst avoiding the need for laparotomy. Stents can also be used to repair damaged vessels.

The interventional radiology suite should have suitable facilities to allow anaesthesia and continued resuscitation of the unstable patient during the procedure. Some centres are now combining an interventional radiology suite and operating theatre to allow simultaneous treatment of multiple injuries with surgery and angioembolisation.[33] This reduces the amount of time taken for resuscitation and definitive treatment of haemorrhage.[34]

Laparotomy

In the unstable patient who requires surgery, all efforts should be made to get the patient to the operating theatre as soon as possible and it may be that imaging such as the CT scan is delayed until after surgery.

Damage control surgery (DCS) is the concept of an abbreviated laparotomy to gain control of haemorrhage and limit contamination rather than definitive treatment of injuries identified. Physiology is prioritised over anatomy and it has been shown to improve survival in critically injured, shocked patients.[35], [36] This limited operating time ensures rapid transit to the intensive care unit (ICU) for continued resuscitation, correction/prevention of the lethal triad of acidosis, hypothermia and coagulopathy and a thorough further examination (with imaging if necessary) of the patient to ensure all injuries are identified. Once physiology is normalised the patient can return to theatre in a planned way for definitive treatment of the injuries identified.[37]

In massive haemorrhage, the four quadrants of the abdomen are packed sequentially to control venous and solid organ haemorrhage. Arterial haemorrhage may require occlusion of the aorta to gain control. To minimise contamination, simple bowel perforations may be repaired and more complex injuries may be resected. Primary anastomosis and/or stoma formation are not done at this point to save time, so the bowel is left in discontinuity. At the end of the surgery, the abdomen is left open, preventing abdominal compartment syndrome, and further surgery will be required.

DCS is not without its complications and has been shown to increase morbidity and length of stay.[36] For these reasons, it should be reserved for those who are truly reaching the end of their physiological reserve. Studies are needed to identify the exact physiological parameters and injury patterns that require DCS to prevent patients from having this type of surgery unnecessarily.[37], [38]

Damage Control Resuscitation

Regardless of the method of haemorrhage control, resuscitation of the patient should start in the pre-hospital phase continuing into the ICU. It is now clear that coagulopathy and hyperfibrinolysis occur early in the disease process of major trauma and these should be addressed early.[19], [39] DCR describes the concept of minimising crystalloid administration, permissive hypotension and a balanced transfusion of 1 : 1 : 1 of clotting factors: platelets: blood to prevent/correct coagulopathy. This method of resuscitation has been shown to increase survival and reduce the overall amount of blood and blood products required.[20], [21], [40-42]

Specific Injuries

Spleen

Alongside the liver, the spleen is the organ most frequently injured by blunt trauma.[31] Injuries vary from a small subcapsular haematoma to hilar devascularisation or shattered spleen and are graded according to the American Association of Surgery for Trauma (AAST) splenic injury scale (I–V). Associated injuries include fractured left-sided ribs, and injuries to the left hemi-diaphragm, pancreas and bowel. Minor injury to the spleen may have few symptoms and other injuries may mask the symptoms. Minor trauma may cause splenic injury when the spleen is enlarged (e.g., from malaria, lymphoma or haemolytic anaemia).

Increasingly, management of splenic injury is conservative in haemodynamically stable patient. Higher-grade injuries with evidence of contrast blush on CT scan can be managed extremely successfully with angioembolisation.[31], [43] If the patient is haemodynamically unstable and proceeding to theatre for laparotomy, 97% of those with splenic injury end up with a splenectomy, though splenic salvage is technically possible. Some studies show benefit to autotransplantation of splenic tissue during splenectomy.[43]

Overwhelming post-splenectomy infection by encapsulated organisms, such as *Pneumococcus,* can occur early or late (even years) after splenectomy in 0%–2% of individuals. Current UK guidelines recommend the administration of pneumococcal vaccine, meningococcal ACWY and B vaccines, and an annual influenza vaccination; in addition to ensuring the patient has received all the routine vaccines according to schedule.[44] These should be given two weeks post-splenectomy or once the patient is well.[45]

Liver

The liver is commonly injured after blunt abdominal trauma, most frequently from motor vehicle collisions. The potential for massive haemorrhage coupled with multiple possible delayed complications means that the morbidity and mortality rate is high with early death most often caused by massive haemorrhage.[46,47] Diagnosis is made either on CT scan or during laparotomy in those too unstable for CT. Injuries range from small subcapsular haematomas to major parenchymal disruption and laceration of hepatic veins or even hepatic avulsion and are graded according to the AAST liver injury scale (I–V). The most commonly identified injury pattern is lacerations to the liver.[22]

Over 80% of patients with blunt hepatic injury are now managed non-operatively, which is up to 100% successful.[46] Management decisions should be based on haemodynamic status, associated injuries and grade of injury. All grades of liver injury in haemodynamically stable patients can be managed non-operatively as long as close observation and the ability to change the management plan rapidly are possible. In patients with active bleeding from hepatic injury who respond transiently to resuscitation, angioembolisation should be the first-line treatment option. For the more unstable patient, or those with additional intra-abdominal injuries needing surgery, a laparotomy is recommended. The aim is to control haemorrhage and bile leaks alongside DCR. Angioembolisation can be used following packing if persistent arterial bleeding is present and resuscitative endovascular balloon occlusion of the aorta (REBOA) may be used in the extremely unstable patient as a bridge to more definite procedures. With the advent of hybrid operating suites, the option of simultaneous operative and non-operative management of these complex patients is possible.[33]

Complications from non-operative management include hepatic necrosis, hepatic abscesses and infected collections, bile leak/biloma abdominal compartment syndrome, haemobilia, biliary peritonitis, biliary fistula and delayed haemorrhage (5%–12%). The complication rate is higher with higher grades of injury.[48]

Gastrointestinal Tract

Injury to the gastrointestinal tract (GIT) is common following penetrating trauma but only occurs in approximately 5% of blunt abdominal trauma.[22] Over 90% of patients with abdominal gunshot wounds have injuries requiring operative management mandating laparotomy, though there may be a small subset of patients in whom this is unnecessary.[13,14] Laparoscopy is used to both identify and treat injuries from penetrating trauma in stable patients when peritoneal violation cannot be excluded.[13] Posterior stab wounds are more challenging as they may damage retroperitoneal structures.

Blunt abdominal injuries include perforation or devascularisation of stomach, duodenum, small intestine, colon and their mesenteries, all of which are difficult to evaluate. Physical signs are often absent or non-specific.[4] E-FAST will identify free fluid in the abdomen, which may be due to an intestinal injury but is unable to differentiate between blood, urine or fluid from the breach of a luminal organ or from a chronic condition such as ascites. It will also not identify retroperitoneal fluid.

CT scan is the imaging of choice to search for injuries to the GIT and its blood supply. There are both specific and non-specific signs on CT scans of injury to the bowel which may be extremely subtle. Some of the specific signs include intramural haematoma, interruption of the bowel wall and extraluminal spillage of enteric contents. Some of the non-specific signs include extraluminal air collection, intraperitoneal fluid, bowel wall thickening, abnormal bowel wall enhancement and abnormal ‘intestinal behaviours’ (variations in tone, motility, shape and location of intestinal loops).[49]

Mesenteric injury ranges from simple contusions to complete traumatic avulsion. Injury to mesenteric vessels and bleeding may lead to bowel ischaemia and infarction, which may require resection of the affected section of bowel. Infarction of the bowel takes time to develop and may not show up initially on the CT scan. Mesenteric ‘fat stranding’ is a non-uniform increase in the density of parts of the mesenteric fat and represents microhaemorrhagic foci. It is a non-specific sign of injury but should raise suspicions of injury to the mesentery and/or bowel.

Uncomplicated bowel injury can usually be managed by primary repair and anastomosis rather than colostomy. A faecal diversion procedure with delayed repair is indicated in significant peritoneal contamination or severe perineal injury or in DCS for speed.

Pancreas

Pancreatic injury is relatively uncommon and is found in approximately 0.3% of all trauma patients.[50] In blunt trauma, the pancreas is compressed against the spinal column, causing crush injury or transection in the region of the neck of the pancreas. It is often associated with injury to other abdominal organs, especially major vascular structures; 50% of penetrating injuries to the pancreas also have a concomitant vascular injury. CT is the most useful initial investigation; however, it is less sensitive in the detection of pancreatic duct injury. Endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP) are the most sensitive methods for diagnosing duct injury, though logistically challenging to obtain in trauma patients.[22, 50] Serum amylase levels are neither sensitive nor specific for injury and may be normal on presentation.

Evidence is scant, however, guidelines recommend non-operative management for low-grade injuries and surgical resection for high-grade injuries. No recommendations are made for the severest of injuries – data are old and morbidity and mortality extremely high.[51]

Complications such as pancreatitis, fistula, abscess and pseudocyst are common with late complications of sepsis, multiorgan failure and respiratory failure occurring after more severe injury.[52]

Kidney and Urinary Tract

Blunt injury to the urinary tract is more common than penetrating injury with up to 3.25% of patients with blunt abdominal trauma having renal injuries.[54] Haematuria, micro- or macroscopic, after abdominal trauma, is a good indicator of injury to the kidneys or urinary tract.[22] Conversely, injuries to the reno-vascular pedicle or ureters may not cause any haematuria and its absence does not rule out renal injury.

Like liver and splenic injuries, renal injuries are graded on the AAST scale, with most injuries, even the higher grades, being managed conservatively.[53-55]

Multi-phase CT is the examination of choice, allowing early, accurate detection of renal tract injury. Urinary extravasation may be identified only on a repeat scan 10–20 minutes after contrast injection or on a formal retrograde (CT) cystogram. Stable patients with renal injury are most often managed conservatively, which avoids unnecessary surgery and nephrectomy and preserves renal function. Immediate intervention is needed in those with instability to stop bleeding and repair the kidney if possible. This may be done with interventional radiology, but nephrectomy is often the end result if the patient undergoes laparotomy. Parenchymal collecting system injuries often resolve without intervention but injury to the renal pelvis or proximal ureter avulsion requires urgent intervention. Non-operative management requires re-imaging to look for complications; however, the optimal timing is not yet clear. Aldiwani et al. routinely performs this at 48 hours in their major trauma centre.[55] Complications such as persistent urinary extravasation, urinoma or sepsis may require treatment with a ureteric stent, percutaneous drainage or percutaneous nephrostomy whereas pseudoaneurysm will need angioembolisation.[54, 55]

Bladder injury is commonly associated with pelvic fractures. Blunt injury to patients with a distended bladder can cause isolated intraperitoneal bladder rupture. Over 95% of patients with bladder injury have macroscopic haematuria. Retrograde cystography is the investigation of choice. Intraperitoneal bladder rupture requires operative repair and urinary drainage, as it is unlikely to heal spontaneously and puts the patient at risk of bacterial translocation causing peritonitis and death. Patients with uncomplicated extraperitoneal injury of the bladder can be managed conservatively with urinary catheter drainage alone.[56, 57]

Urethral trauma is caused by direct blunt trauma or in association with pelvic fractures, particularly those involving pubic diastasis in males.[23] It should be suspected if there is blood at the urethral meatus, perineal injury or abnormal position of the prostate on rectal examination. If there is suspicion of urethral injury, retrograde urethrography should be performed. One gentle attempt at urethral catheterisation by an experienced operator is acceptable, and if this is unsuccessful, then suprapubic catheterisation should be performed by the urologists in conjunction with pelvic surgeons. The timing of definite repair should be organised in conjunction with any required surgery to repair pelvic fractures.

Diaphragm

Diaphragmatic injury occurs in fewer than 5% of cases of blunt injury, is left-sided in 80% of cases, and is rarely an isolated injury. It should be suspected in any penetrating thoracic or abdominal trauma. Diagnosis can be difficult, with up to 50% of chest X-rays having non-specific findings or no abnormality. CT scan has a sensitivity of 61%–87% and specificity of 72%–100% in diagnosing diaphragmatic injury.[58] Multiplanar reconstruction of the images improves this accuracy further. Mortality is high (30%–60%) in those that are initially missed and present late with intrathoracic strangulation of a herniated viscus.[59]

If there is radiological suspicion of diaphragmatic injury in the stable patient, a diagnostic laparoscopy should be performed to confirm the diagnosis.[59] Spontaneous healing does not occur, and all defects over 1 cm should be repaired. The risk of associated injuries means that an abdominal approach is most often used.

Bony Pelvis and Perineum

Pelvic fractures in younger adults are primarily caused by high-energy blunt trauma such as RTCs or falls from height; in older adults, they are more likely to be due to low-energy falls from standing. Associated injuries are common, to pelvic organs such as the bladder and urethra but also to elsewhere in the body such as head and thoracic injuries. Injuries may be life-threatening and mortality is up to 34% in patients with pelvic fracture and haemodynamic instability.[23, 60] Pelvic injury should be suspected in any high-energy injury and is suggested by pain on movement or in the hips, tenderness in the sacral or suprapubic areas, shortening and/or external rotation of a lower limb, gross haematuria or peri-pelvic ecchymosis.

CT is the best mode of imaging to rapidly identify pelvic fractures, any associated injuries or bleeding which may be amenable to angioembolisation. Reconstruction of the images will also aid in planning the definitive operative fixation of complex fractures. E-FAST in the resuscitation room may identify any intra-abdominal bleeding but will not show associated retroperitoneal haemorrhage.

Pelvic injury is often graded using the Young and Burgess classification where fractures are classified based on the type of force causing the subsequent injury – lateral compression, anterior-posterior compression or vertical shear. Each of these is then subdivided based on the severity of ligamentous disruption. An alternative method of classification is the Tile method.[60]

Patients with anterior-posterior compression fractures (‘open-book’) are more likely to have massive haemorrhage than those with lateral compression fractures, but haemorrhage is always a potential with pelvic fractures and should be identified and treated early.[61] Time to control of haemorrhage has a direct effect on mortality.[62] The management of these patients is difficult and there is no consensus as to what is the best management of the haemodynamically unstable patient with a pelvic fracture. The application of a temporary pelvic binder is often done in the pre-hospital phase but should be performed in the emergency department otherwise. It reduces bleeding by approximating fracture sites and preventing clot dislodgement by improving stability. The volume of the pelvis doesn’t significantly increase when fractured; therefore, there is no tamponade effect from reducing pelvic volume with the binder as originally thought.[60] Although most bleeding in pelvic fractures is venous rather than arterial, in unstable patients, arterial bleeding is more common.[60, 61] Angioembolisation, pre-peritoneal pelvic packing and pelvic fixation devices are all used to stabilise and stop massive haemorrhage associated with pelvic fractures. There is no consensus yet on the optimal management strategy for these patients however there is a general move towards angioembolisation as a first-line strategy which is extremely successful for arterial bleeding.[32,61,62]

The majority of patients with a pelvic fracture are haemodynamically normal with a stable fracture and moderate ligamentous disruption. These should be fixed on a non-urgent, planned basis within 72 hours.[63] Early operative stabilisation of complex pelvic fractures is preferred in the ICU and can be done externally, internally or as a combination of both; it facilitates respiratory care, pain control and early mobilisation. There is also growing evidence that operative management of pelvic fractures has a better functional outcome in the long term.[60] Compound pelvic fractures involving the perineum, rectum or vagina require early aggressive surgery (which may include diversion of the faecal stream) to avoid high mortality.

Early deaths (in the first 24 hours) are due to haemorrhage, whereas late deaths are more commonly due to the systemic inflammatory response (SIRS) to trauma and multiorgan failure.[60]

Trauma in Pregnancy

The most common causes of trauma in pregnant women include RTCs, assaults and falls.[64] Women injured during pregnancy pose challenges of altered physiology, risk to the gravid uterus and foetus, and potential conflict of priorities between mother and foetus. In general, however, the best treatment for the foetus is to treat the mother optimally, which, with major trauma, is a rapid, systematic evaluation of the patient with concurrent treatment of life-threatening emergencies. It must be remembered that the placental blood flow is dependent on maternal arterial blood pressure and has no autoregulation.

The mother should be placed in a left lateral tilt from the start to prevent aortocaval compression and high-flow oxygen should be given until maternal hypoxaemia, hypovolaemia and foetal distress have been excluded. Altered maternal physiology means that shock can be more difficult to detect:

- Increased maternal blood volume by up to 50% with physiological anaemia due to haemodilution
- Increased cardiac output with increased heart rate, reduced systemic vascular resistance and reduction in mean arterial pressure
- Increased respiratory rate and tidal volume with increased oxygen consumption and reduced functional residual capacity and reduced $PaCO_2$; meaning little respiratory reserve if demand increases due to injury and rapid onset of hypoxia
- The uterus is protected by the pelvis up to 12 weeks of pregnancy, after which it encroaches into the peritoneal cavity, displacing maternal organs and becoming more susceptible to injury
- Increased volume of stomach acid, reduced lower oesophageal sphincter tone and reduced gastrointestinal motility, increasing the risk of aspiration
- Pregnancy-induced changes in the airway, coupled with less respiratory reserve, make rapid sequence induction of anaesthesia and intubation of the trachea more difficult in pregnancy. [65]

When considering imaging, the radiation risk to the foetus should be weighed up against the risk to mother and foetus of missing an injury. Imaging that is the standard of care in a non-pregnant patient with potentially life-threatening injuries should remain the same in the pregnant patient. [64] E-FAST is safe in pregnancy and in addition to detecting free fluid in the abdomen, the condition of the foetus can also be assessed.

The injury pattern can change due to the presence of the gravid uterus. There is upward displacement of bowel with the potential for complex intestinal injuries in penetrating trauma of the upper abdomen. The pelvic vasculature is hypertrophied with the potential for massive retroperitoneal haemorrhage in pelvic injury. Similarly, the blood supply to the uterus at term is 600 mL/min, meaning there is potential for massive haemorrhage with direct uterine injury. Placental abruption can occur, which may conceal significant blood loss.

Early involvement of the obstetric team is crucial for management decisions and for ongoing monitoring of the materno-foetal unit. Treatment may be expectant or by caesarean section, depending on the condition of the mother and foetus. Uterine rupture is unusual and will often require a hysterectomy. In traumatic cardiac arrest, perimortem caesarean section should commence as soon as possible but within 4 minutes for the best outcome for mother and foetus.[66]

Following maternal trauma, there is increased risk to the foetus both in the short and long term, especially with more severe trauma. Placental abruption, foetal distress and foetal loss can all occur, as can premature labour.[66] Continuous cardiotocography (indicated at viable gestations) is recommended for all trauma patients to assess foetal well-being and the Kleihauer–Betke tests to identify foeto-maternal haemorrhage have been used to predict patients at high risk for preterm delivery and adverse perinatal outcomes.[64] All Rhesus-negative pregnant women who suffer trauma should receive immunoglobulin because of the immunological risk of even minor foetal-maternal haemorrhage.

Complications

Haemorrhage and Coagulopathy

Haemorrhage from injuries due to major trauma is the most common cause of preventable trauma death.[5,6] Acute traumatic coagulopathy (ATC) occurs in up to 35% of patients by the time they arrive at hospital and is associated with significant tissue injury and shock. Endogenous anticoagulation develops in response to the increasingly more procoagulant vasculature due to damaged endothelium. This anticoagulation is due to autoheparinisation, activation of protein C and hyperfibrinolysis. ATC is then worsened by acidosis and hypothermia. Finally, the administration of fluids other than blood products further compounds this by causing a dilutional coagulopathy.[19,21,35,39,40]

Treating the massive haemorrhage and coagulopathy associated with major trauma is challenging. DCR, initially developed in the military, should be commenced in the pre-hospital phase. DCR incorporates permissive hypotension, early treatment of the anticipated ATC with the use of blood and blood products, avoiding the use of crystalloids and early use of tranexamic acid.[35,41,42] Evidence shows that DCR improves outcomes and reduces complications from DCL and may also reduce the number of patients requiring DCL who can instead have immediate definitive treatment.[41] Equally as important as the treatment of coagulopathy and shock is haemorrhage control using DCS or angioembolisation.

Permissive hypotension aims to avoid the adverse effects of aggressive fluid resuscitation – dilution of clotting factors, hypothermia, increased intraluminal pressure at the site of injury causing dislodgement of clot – whilst maintaining some tissue perfusion for a short period of time, and has been shown to improve mortality in hypotensive trauma patients.[67] There is little evidence to say what mean arterial pressure is acceptable in this situation, but European guidelines recommend a systolic blood pressure of 80–100 mm Hg, whereas NICE and others recommend a mean arterial pressure of 50 mm Hg or the presence of a central pulse.[25,35,68] Permissive hypotension is contraindicated in the presence of concurrent neurological injury where perfusion and oxygenation of the injured brain or spine take priority.[25,67]

To address ATC, transfusion with blood and blood products in a 1 : 1 : 1 (plasma: platelets: red cells) compared to a 1 : 1 : 2 ratio has been shown to improve haemostasis and lead to fewer deaths due to exsanguination in the first 24 hours, although there was no overall improvement in 24-hour or 30-day mortality.[40] This has now been incorporated into guidelines along with the use of major haemorrhage protocols allowing rapid access to blood and blood products.[19,25,35] TEG and ROTEM are now routinely used to guide massive transfusion in trauma and provide a more bespoke patient-specific transfusion of blood and products. There is evidence of improved survival compared to conventional measures of coagulation and of a reduction in total products used.[21,25,69]

Administration of the antifibrinolytic tranexamic acid within 3 hours of injury has been shown to reduce deaths from bleeding without increasing vascular occlusive events in a large study of patients treated in diverse hospital settings.[42] It is commonly given pre-hospital now but should be given as early as possible in the resuscitation room if not.[19,25,35]

As trauma in the elderly is increasing, it must be remembered that patients may also be on long-term anticoagulation which may contribute to haemorrhage. This should be identified early and the agent reversed as soon as possible. [25]

Open Abdomen Following Damage Control Surgery

After DCS, patients are admitted to the ICU with temporary closure of the abdomen. Once their physiology is normalised, they will return to theatre, often several times, for definitive management of the injuries and closure of the abdomen. An open abdomen puts patients at risk of ischaemia-reperfusion injury to the bowel and acute respiratory distress syndrome associated with this; they are also likely to develop a SIRS. [70]

Sepsis and Entero-Cutaneous Fistula

Entero-cutaneous fistula (ECF), an abnormal communication between the intra-abdominal GIT and the atmosphere, is a significant problem with high morbidity and mortality. [71] It causes multiple complications including sepsis, fluid loss, electrolyte abnormalities, prolonged ICU and hospital stays and complex wound care issues. They are difficult to manage and usually require operative repair. Predisposing factors include:

- Bowel resection
- Bowel left in discontinuity
- Those administrated a large amount of fluids during the first 24 hours
- Multiple abdominal re-explorations
- Delayed closure of an open abdomen. [72]

Early diagnosis and effective lavage and drainage procedures may reduce the incidence of intra-abdominal sepsis. In the absence of sepsis, prophylactic antibiotics for 24 hours are satisfactory for open abdomens after DCS. Infectious complication rates correlate directly with time to fascial closure.[70]

Ventral Hernia

Up to 80% of patients with an open abdomen go on to develop a ventral hernia after delayed fascial closure. This may be planned if there is no other way to close the abdomen.[71] Large ventral hernias may prolong recovery due to discomfort or loss of function. They may be repaired at a later stage with reconstruction of the abdominal wall.

Fluid Loss and Electrolyte Imbalance

Patients lose large amounts of fluid from the peritoneal cavity resulting in electrolyte imbalance and dehydration. Fluid management after the initial resuscitation is challenging, as excess fluids may lead to increased complications with bowel wall oedema, anastomosis breakdown and abdominal compartment syndrome. Conversely, these patients often require extra fluids due to the open peritoneal cavity and SIRS from the trauma.

Malnutrition

These patients are highly catabolic and can lose large amounts of protein through the open abdomen. Malnutrition is particularly common in those who develop ECF.[70], [71] Nutritional support is crucial and often challenging. Enteral feeding should be commenced early in those with intact intestinal continuity and no obstruction. In those who do not have intestinal continuity (delayed repair of bowel injuries) or have complex injuries, parenteral nutrition is required.

Abdominal compartment syndrome is discussed in Chapter 74 : Post-operative major abdominal surgery

Venous Thromboembolism

Pelvic trauma, postoperative status, higher Injury Severity Score and underlying medical risk factors increase the risk of venous thromboembolism 1.5–3 times greater than trauma patients without such factors.[73] Early initiation of mechanical prophylaxis is usually feasible, as is pharmacological prophylaxis when the risk of injury-associated bleeding has reduced. Inferior vena cava filters can be used in trauma patients where pharmacological prophylaxis is contraindicated and reduces the incidence of pulmonary emboli, however, it is not yet clear which patients benefit most and there are significant complications related to these devices.[74]

Intensive care and the elderly

Linsey Emma Christie and Richard T. Keays

The proportion of the elderly population is increasing in all developed and developing nations. Likewise, the median age of patients in the intensive care unit (ICU) has been steadily rising over the last few decades. The elderly may have age-acquired co-morbidities, increased frailty, reduced activities of daily living, reduced mobility and reduced cognition. The ethical decisions related to whether admission is appropriate, as well as withdrawing and withholding of life support, can be difficult. [1] This chapter seeks to bring together the current information on the management of the elderly presenting to critical care.

Definitions

There is no agreed definition of ‘elderly’. It has been defined by chronology, social role, physical capacity, threshold life expectancy and when ‘active contribution is no longer possible’. Most commonly, it is taken as the pension age of 65, but this is an inherently fluid end-point, as the pension age in the United Kingdom has gradually increased to 66 from 2018 to 2020 and will continue to rise. In 1875, the over-50s were defined as elderly. The over-80s are also becoming an ‘identifiable’ group. These chronological niceties are rarely relevant from a medical perspective, as clinicians understand the poor correlation between chronological and physiological age. The medical literature has no common definition and uses a wide range of arbitrary values from 67 to 70, over-70s and, more recently, over-80s to describe population groups. [2]

Demographics

More people are living longer and this trend has shown little sign of stopping. In the United Kingdom, the number of people aged 65 years and over has increased from 9.2 million in 2011 to over 11 million in 2021 and the proportion of people aged 65 years and over rose from 16.4% to 18.6%. [3] The coronavirus pandemic led to a greater number of deaths than normal in 2020. Consequently, in the 2018–2020 National Statistics report, there was virtually no improvement in life expectancy for females compared to 2015–2017 at 82.9 years, while for males, life expectancy had fallen back to levels reported for 2012–2014, at 79 years. This is the first time there has been a decline. [2] In the United Kingdom, the proportion of the population estimated to be over 65 by 2060 is 26%, [4] compared to 2011 when it was 16%. [5]

In Europe, 20.3% of the population was over 65 years old at the start of 2019 and this percentage is expected to increase to 30% by 2070. [1] Worldwide, the situation is similar. The 2023 United Nations World Social Report states that the number of people aged 65 years or older worldwide is projected to more than double, from 761 million in 2021 to 1.6 billion in 2050. [6]

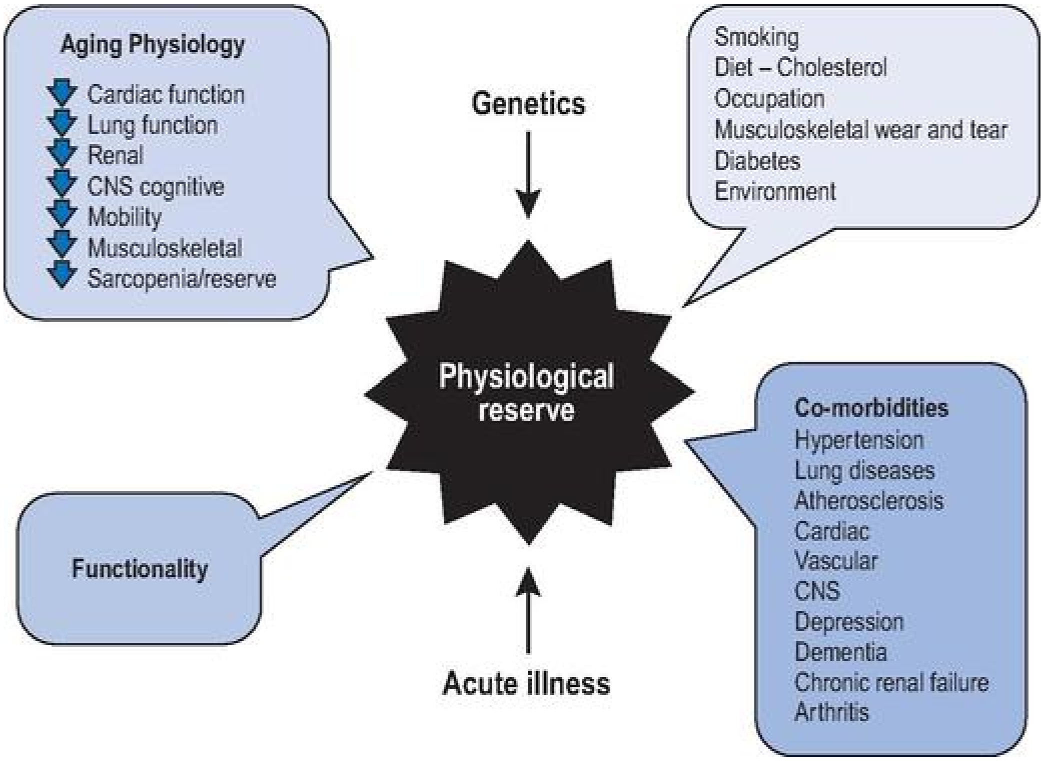
The post-war increase in longevity means many more elderly people present to critical care than previously. This greater longevity may be attributable to improved diet and better lifestyle decisions but is also explained by improved disease management; however, the resultant gain in survival is at the price of living with morbidity. Not only are there more elderly patients but also, but they also have more significant co-morbidity and thus a greater likelihood of developing a critical illness.

In 2023, the number of ICU beds per 100,000 population was 6.6 for the United Kingdom, 34.7 for the United States, 29.2 for Germany, 12.5 for Italy and 1.6 for Sri Lanka. [7] A study comparing the United States with the United Kingdom in terms of hospitalisation and the elderly found that 47% of British over-85s died in hospital, whereas this figure was only 31% in the United States; however, only 1.3% of these patients received intensive care in the United Kingdom compared with 11% in the United States. [8] Of all hospital discharges, only 2.2% of patients had received intensive care in the

United Kingdom compared with 19.3% in the United States. Approaching the problem from a different direction is to consider what happens to a whole cohort of elderly people. One such longitudinal study from America following over 1 million elderly patients over 5 years found that over half were admitted to a higher dependency care unit at some point. [9]

The Ageing Process

Individuals accumulate co-morbidities with pathophysiological consequences as they age, but these physiological changes are both unpredictable and extremely variable across any population. Ageing is the combination of physiological change and accumulated pathophysiology (Fig. 83.1). Examples of physiological changes associated with ageing include maximal oxygen uptake, cardiovascular function, muscle mass, tissue elasticity, memory and reaction time, but there are many more. [10]



Aging Physiology

The conceptual diagram shows physiological reserve at the centre. Arrows point toward it from five surrounding elements. At the top, an arrow labelled genetics points at physiological reserve. On the upper right, a speech bubble lists lifestyle and environmental factors, such as smoking, diet and cholesterol, occupation, musculoskeletal wear and tear, diabetes, and environment. On the lower right, a shaded box lists comorbidities, such as hypertension, lung diseases, atherosclerosis, cardiac, vascular, C N S, depression, dementia, chronic renal failure, and arthritis. At the bottom, an arrow labelled acute illness points upward at physiological reserve. On the left, an arrow labelled functionality points toward physiological reserve. The upper left contains a shaded box titled aging physiology with a list of declining functions, such as cardiac, lung,

renal, C N S cognitive, mobility, musculoskeletal, and
sarcopenia or reserve.

FIG. 83.1 Factors affecting physiological reserve. *CNS,* Central nervous system.

The Organ Systems

Each organ system undergoes age-related decline; however, in addition, there are specific disease-related organ alterations leading to a net impairment of organ function. A brief overview of changes associated with age and the impact of the more common co-morbidities follows.

Cardiovascular Changes

The heart has reduced contractility and overall mechanical efficiency [11] caused by:

- altered connective tissue compliance due to interstitial collagen being laid down
- reduction in myocyte numbers
- valve hardening and sclerosis, which can affect function
- fibrosis and cell loss in conduction pathways impairing conduction
- deterioration in the sinoatrial node
- ventricular hypertrophy with slower myocardial relaxation.

The result of these changes is a reduction in arterial compliance with an earlier return of the reflected wave in systole. Normally, cardiac pulsatile energy is absorbed at the arteriolar segmental level in the young but not in the elderly. Aortic impedance increases and higher blood flow organs show familiar signs of microvasculopathy. This, coupled with the tendency for pulse pressure to rise with age, means that ventricle hypertrophy and cardiac work increase. The resultant increased oxygen demand occurs against a background fall in diastolic coronary blood flow with ventricular hypertrophy.

Both contraction and relaxation phases are slower. Diastolic-filling time is reduced, which places an extra emphasis on the atrial component to maintain this filling resulting in a reversal of the E/A ratio (early-to-late diastolic-filling velocity). Subsequent atrial dilatation is more likely to lead to atrial fibrillation, significantly compromising ventricular filling. The smaller end-diastolic volume is poorly tolerated, and impaired cardiac performance ensues.

In addition to these changes, coronary flow reserve is limited, blood vessels are less easily dilated and there is a chronically elevated basal sympathetic tone. Baroreceptor reflexes are impaired and there is decreased sodium conservation.

In summary, the main ageing changes are myocardial and vascular stiffening, with impaired cardiac and vascular compliance. The blunted sympathetic responses produce the ‘hyposympathetic heart’ with a tendency to increase end-diastolic volume. Additionally, there is an age-related reduction in cardiac contractility. Overall cardiac reserve and flexibility of response are reduced, but are usually more than able to deal with the normal physical requirements of the elderly – though not with more excessive demands (Box 83.1).[11,12]

Box 83.1

Cardiovascular ageing

Cellular changes: reduced excitation-contraction coupling, calcium homeostasis, myocyte function and increased atrial natriuretic peptide

Decrease in myocytes, altered connective tissues, increased ventricular wall size

Reduction in conductive tissues and number of sinus node cells

Decreased contractility, reduced ventricular compliance, increased ventricular filling pressure, blunting of β-adrenoceptor responsiveness, reduced coronary flow reserve

Stiffer arteries, reduced elasticity

Thicker media and intima

Alterations in autonomic tone with reduced β-adrenoreceptor-mediated vasodilatation; reduced NO activity

Reduced heart rate, increased end-diastolic volume, increased stroke volume, reduced peak values for ejection fraction, cardiac output

Impaired conduction, atrial fibrillation

Clinical effects: more arrhythmias, hypertension, reduced exercise tolerance, dyspnoea and heart failure

Acquired Cardiovascular Disease

Atherosclerosis is detectable much earlier in life and starts to become relevant around 40 years of age in males and after menopause in females. For people older than 65 years, 40% of deaths are cardiovascular and this increases with age. Diabetes, smoking, poor blood pressure control and high cholesterol all increase the risk of death from cardiovascular disease and most become more common with age. [13] Myocardial infarction carries a higher mortality in the elderly and the risk associated with interventional treatments is also higher. [11], [12] The Framingham study showed that 40% of myocardial infarctions in those over 75 were silent. [14] In addition, arrhythmias, such as atrial fibrillation, are more common as a chronic feature in the elderly but most particularly affect the postoperative patient. In one study, 22% of over 70-year-olds developed postoperative atrial fibrillation. [15] When it does occur, patients may be more at risk from hypotension, cardiac failure and myocardial infarction. The most common cause of death amongst the over-85s in the postoperative period is myocardial infarction. [16]

Respiratory

Lung function decline starts at around the age of 35 years. Muscle function is impaired by a combination of reduced fast twitch fibres and muscle atrophy, so between the ages of 65 and 85, there is a decrease in maximum inspiratory pressure, maximum voluntary ventilation and forced expiratory volume in one second (FEV_1). Impaired diaphragmatic strength impacts the force of coughing. Degeneration of elastic fibres in the lung parenchyma leads to air space enlargement. Chest wall compliance is reduced and a rise in closing volume results in increasing V / Q mismatching. This whole effect has been termed ‘senile emphysema’ and is often accompanied by age-related β-receptor dysfunction.

Gas transfer is also affected – the diffusing capacity of the lungs for carbon monoxide (DLCO) declines with some impairment of oxygenation (about 0.5 kPa/decade) but there is no discernible effect on carbon dioxide clearance. Both the hypoxic and hypercapnic respiratory control responses are blunted. Exercise capacity, as shown by maximal velocity (V_{max}), declines by about 1% per year after the age of 30. [16-18]

Less direct intrinsic and extrinsic changes also occur that will impair respiratory function. Diminished antioxidant defences have been observed and bronchial lavage sampling shows changes in both immunoglobulin and CD4/CD8 ratios implying chronic antigenic stimulation. There is also an increasing age-related burden of problems, such as nocturnal gastroesophageal reflux, kyphosis, vertebral collapse and sleep apnoea. The likelihood of environmental exposure to agents with the potential to cause lung damage, most particularly tobacco smoke, increases with age.

Hence it is predictable not only that more elderly patients will require respiratory support but also that ventilatory weaning is going to be more challenging. Mortality is also likely to be higher compared with younger populations. An American study confirms that the likelihood of requiring ventilation does increase with age, with an estimated 10% chance in the over-75s. [19] Amongst those who are ventilated, mortality in the over-70s is nearly double that in the under-40s, [20] and there is a high 3-year mortality in those discharged from the ICU with 57% of deaths occurring early after discharge. [21] This bleaker picture is offset to some extent in those with chronic obstructive airway disease; patients with acute exacerbations have a lower mortality at 28% compared with other causes of respiratory failure. Nevertheless, even among ICU survivors in this group, the extent of pre-morbid problems and the need for ongoing care at discharge dictates the outcome; if they were not fit to go directly home then mortality is higher [22] and a high proportion will still need help with at least one activity of daily living, and the quality of life scores are low – though not necessarily lower than they were pre-morbidly.

Renal

Kidney size becomes smaller with age due to a reduction in the number of nephrons; 20% to 30% of glomeruli become sclerotic and the glomerular filtration rate may diminish by 50% by 80 years of age. However, this is neither consistent nor predictable. [23] Not only does creatinine clearance start to decline from the fourth decade of life, but renal blood flow also decreases by about 10% per decade. Tubular exchange of sodium and hydrogen ions is also reduced, with impaired ability to handle fluid loads and acidaemia. Rarely is this ever seen as a clinical or biochemical entity, but it does represent a reduction in reserve capacity and manifests only when acute stressors are applied. In the elderly, the competing needs of the kidney versus the heart make the treatment of incipient failure of either organ problematic and failure of one organ can cause the failure of the other – this has been termed ‘cardiorenal syndrome’. [24]

The risk of developing acute kidney injury increases with age and is especially associated with co-morbidities such as cardiac failure and renovascular disease, and acquired preconditions such as known nephrotoxic drugs, surgical interventions and sepsis. Obstructive uropathy may be a consequence of the increasing prevalence of prostatic disease. Many drugs have been implicated, but non-steroidal analgesics and angiotensin-converting enzyme (ACE) inhibitors stand out. Surgery involves acute changes to blood pressure and volume status but carries the additional risk of abdominal hypertension.

There is an attributable mortality associated with acute kidney injury, though it is difficult to tease out. It appears that this may be similar between the young and the old [25] and has been variously quoted at between 15% and 40%. The outcome from acute kidney injury is determined by cause and prior functional status, with drug-related renal failure doing better than most other causes. The mean survival of octogenarians after an episode of acute renal failure was 19 months, but complete recovery of renal function occurs in just over half of the survivors. [26] In one study, only 3 out of 23 biopsies of acute kidney injury showed evidence of acute tubular necrosis. [27] Those with pre-existing chronic renal failure are seven times more likely to progress to long-term dialysis. [28]

A secondary but important effect in the elderly is that there is often a reduced ability to excrete drugs. The consequence may be prolonged half-life (by a factor of 1.4), altered volumes of distribution (+24%) and reduced clearance. [29] This is probably a source of excess morbidity in the elderly.

Liver

The liver is relatively unaffected by age and has huge intrinsic reserves so a reduced mass of up to 30% at 80 years probably has little effect, other than loss of reserve. There is a tendency to reduce liver blood flow by up to 40% at 80 years and reduced metabolic function, in particular demethylation and the production of cholinesterase. It may have some effect on drug handling but is rarely of clinical relevance.

It is acquired liver disease (most commonly cirrhosis) that is the potent predictor of mortality, and this has a peak age of presentation in the sixth or seventh decades of life. Nevertheless, age itself is not a poor prognostic indicator in the context of patients with cirrhosis requiring intensive care. [30]

Central Nervous System

There is often some decline in cognitive performance with age, though this is contentious. Memory loss is apparent in 10% of those over 70 years of age and about half of these are due to some variant of Alzheimer disease. This incidence doubles with each decade. [10] The neurocognitive decline is multifactorial but is associated with cerebral vasculopathy, decline in sex steroids, neurochemical alterations such as melatonin and sleep disorders, which are common in the elderly. Dementia has strong associations with cerebral vascular pathology and strokes, but previous head injury is also important. A new era of dementia treatment is imminent and may alter the ICU perspective on the irreversibility of this condition.

Unsurprisingly, patients with neurocognitive decline are much more likely to experience delirium. Up to two-thirds of patients aged over 65 years experience delirium in hospital and, in the ICU, one-third of patients are admitted with it and one-third develop it following admission. [31] Delirium is common after major surgery and trauma; for example it occurs in up to 60% of patients following a hip fracture. Delirium can lead to long-term cognitive impairment, [32] lengthens hospital stay and is an independent predictor of 6-monthly mortality. [33]

Age is a risk factor for persistent psychological issues and part of this may be related to post-traumatic stress disorder.

Psychological assessment of the elderly during and post-intensive care is in its infancy. The existing tools for assessing delirium are the Confusion Assessment Method for ICU (CAM-ICU) and the Intensive Care Delirium Screening Checklist (ICDSC). CAM-ICU is often used in the ICU and gives a positive or negative result for the presence of delirium. An ICDSC score of more than 4 correlates with both increased mortality and, in survivors, persistent cognitive dysfunction. More recently, the 10-risk-factor assessment tool PREdiction of DELIRium in ICu patients (PRE-DELIRIC) has been validated for the ICU. [34] With increasing awareness and detection of delirium, appropriate interventions can be implemented for both prevention and treatment.

Metabolic

Over the age of 70, there is a tendency for weight loss with a general change in body composition, leading to increased fat and reduced muscle mass. This sarcopenia is manifested by a 30% reduction in main muscle group strength by the seventh decade of life. [35] With less musculoskeletal activity, there is less energy use, less heat production and a reduced calorie requirement with a 2% decrease in basal metabolic rate (BMR) per decade. Protein requirements stay broadly the same.

Malnutrition is common and calorific intake is often inadequate. This ‘anorexia of ageing’ is multifactorial and is not just psychosocial – there are some fundamental physiological changes: early satiation is common and gastric emptying is delayed with the feeling of fullness suppressing ghrelin, thereby reducing appetite, as do raised cholecystokinin levels, which are also common. Dehydration and micronutrient deficiencies are also frequent. Loss of water-soluble vitamins such as thiamine occurs with diuretic therapy. B12 deficiency occurs due to atrophic gastritis and reduced intrinsic factor secretion. Calcium and vitamin D deficiency is also common in the elderly.[36]

Weight loss, frailty and reduced functional capacity will predispose to morbidity, complications, survival and in survivors, it will reduce the ability to regain independence.

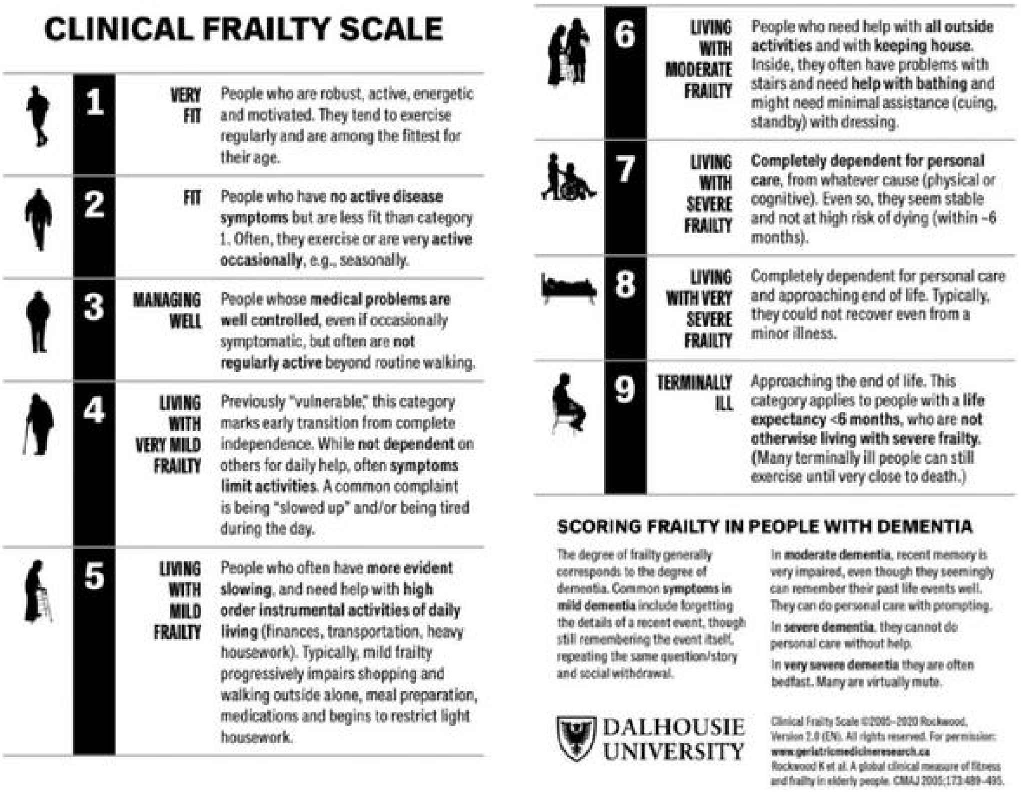
Special Considerations

Having discussed the organ system considerations both in terms of the physiological process of ageing and the acquisition of co-morbidities, it is notable that some elderly patients may also have additional issues, such as frailty or a disability, which can affect care. While in many ways the elderly have the same requirements as any other ICU patient, these other areas do require special attention.

Frailty

It is vital to consider in more detail the concept of ‘physiological age’ versus ‘chronological age’ – essentially frailty. Frailty has been defined as ‘a condition characterised by loss of biological reserve and vulnerability to poor resolution of homeostasis following a stressor event’.[37] One method of frailty assessment is the 7-point Clinical Frailty Scale (CFS) (Fig. 83.2).[38]

Clinical Frailty Scale



CLINICAL FRAILTY SCALE

1	**VERY FIT**	People who are robust, active, energetic and motivated. They tend to exercise regularly and are among the fittest for their age.
2	**FIT**	People who have **no active disease symptoms** but are less fit than category 1. Often, they exercise or are very **active occasionally**, e.g., seasonally.
3	**MANAGING WELL**	People whose **medical problems are well controlled**, even if occasionally symptomatic, but often are **not regularly active** beyond routine walking.
4	**LIVING WITH VERY MILD FRAILTY**	Previously "vulnerable," this category marks early transition from complete independence. While **not dependent** on others for daily help, often **symptoms limit activities**. A common complaint is being "slowed up" and/or being tired during the day.
5	**LIVING WITH MILD FRAILTY**	People who often have **more evident slowing**, and need help with **high order instrumental activities of daily living** (finances, transportation, heavy housework). Typically, mild frailty progressively impairs shopping and walking outside alone, meal preparation, medications and begins to restrict light housework.
6	**LIVING WITH MODERATE FRAILTY**	People who need help with **all outside activities** and with **keeping house**. Inside, they often have problems with stairs and need **help with bathing** and might need minimal assistance (cuing, standby) with dressing.
7	**LIVING WITH SEVERE FRAILTY**	**Completely dependent for personal care**, from whatever cause (physical or cognitive). Even so, they seem stable and not at high risk of dying (within ~6 months).
8	**LIVING WITH VERY SEVERE FRAILTY**	Completely dependent for personal care and approaching end of life. Typically, they could not recover even from a minor illness.
9	**TERMINALLY ILL**	Approaching the end of life. This category applies to people with a **life expectancy <6 months**, who are **not otherwise living with severe frailty**. (Many terminally ill people can still exercise until very close to death.)

SCORING FRAILTY IN PEOPLE WITH DEMENTIA

The degree of frailty generally corresponds to the degree of dementia. Common **symptoms in mild dementia** include forgetting the details of a recent event, though still remembering the event itself, repeating the same question/story and social withdrawal.

In **moderate dementia**, recent memory is very impaired, even though they seemingly can remember their past life events well. They can do personal care with prompting.

In **severe dementia**, they cannot do personal care without help.

In **very severe dementia** they are often bedfast. Many are virtually mute.

Rockwood K et al. A global clinical measure of fitness and frailty in elderly people. CMAJ 2005;173:489–495.

The nine-point clinical frailty scale, titled Clinical Frailty Scale, displays nine categories with corresponding descriptions. The scale ranges from 1 to 9. Category 1 is labelled Very Fit, describing people who are active and among the fittest for their age. Category 2 is Fit, which refers to no active disease symptoms with occasional activity. Category 3 is Managing Well, for people with well-controlled medical problems who are not regularly active. Category 4 is Living with Very Mild Frailty, marking early signs of slowing and some limitations. Category 5 is Living with Mild Frailty, describing individuals needing help with higher-order daily activities. Category 6 is Living with Moderate Frailty, needing help with all outside activities and minimal help with bathing and dressing. Category 7 is Living with Severe Frailty, completely dependent for personal care but stable. Category 8 is Living with Very Severe Frailty, completely dependent and unable to recover from minor illness. Category 9 is Terminally Ill, approaching the end of life with a life expectancy under six months. A side section titled Scoring Frailty in People with Dementia explains how the scale corresponds to the degree of dementia and describes variations in memory, social withdrawal, and personal care ability. The chart includes a footer crediting Dalhousie University and the authors of the scale.

FIG. 83.2 Clinical frailty score.

A study of 1040 ICU patients demonstrated that greater CFS scores were independently associated with greater mortality at 3 and 12 months follow-up, and with greater odds of disability in instrumental activities of daily living. [39] Likewise, the COVIP study and others, showed frailty was independently associated with lower survival. [40-43] A meta-analysis of 10 observational studies also showed that frailty was associated with higher hospital and long-term mortality and patients were less likely to be discharged home. [44] Therefore identification of frailty may help with prognostication and intervention in this high-risk group.

Disability

Some elderly patients may also have a disability that can affect care (e.g. hearing or vision loss).

Pharmacology

There are marked changes in pharmacokinetics and pharmacodynamics in the elderly. Due to the impaired ability of the kidneys to excrete drugs, drug half-lives may be prolonged. The volume of distribution may also either increase or decrease depending on the drug and the changes in body composition. [29] For example, the aminoglycosides not only may achieve higher concentrations than predicted through distribution changes but also may remain higher for longer due to impaired excretion. Non-steroidal anti-inflammatory drugs may have profound and potentially toxic effects by the potent combination of a relatively smaller volume of distribution and the possibility of relative dehydration producing high drug levels; the associated drug-related inhibition of the prostaglandins would promote renal vasoconstriction, reducing renal blood flow and resulting in renal toxicity.

There may be changes in sensitivity to drugs, partly through altered pharmacokinetics as described, or through interaction with physiology, such as the decline in sensitivity to beta-adrenergic agonists and antagonists with age. By a similar mechanism, there is an increased incidence of orthostatic hypotension with antihypertensive drugs. The central nervous system, however, becomes more sensitive to centrally acting drugs.

Fluid management must incorporate some general considerations. These include the potential presence of both cardiovascular and renal impairment (cardiorenal syndrome), a reduced flexibility in cardiac output and an increasing dependence on alterations in systemic vascular resistance. This, along with changes in body composition, may alter fluid distribution. However, it is unpredictable across the population and therefore should be assessed in the individual.

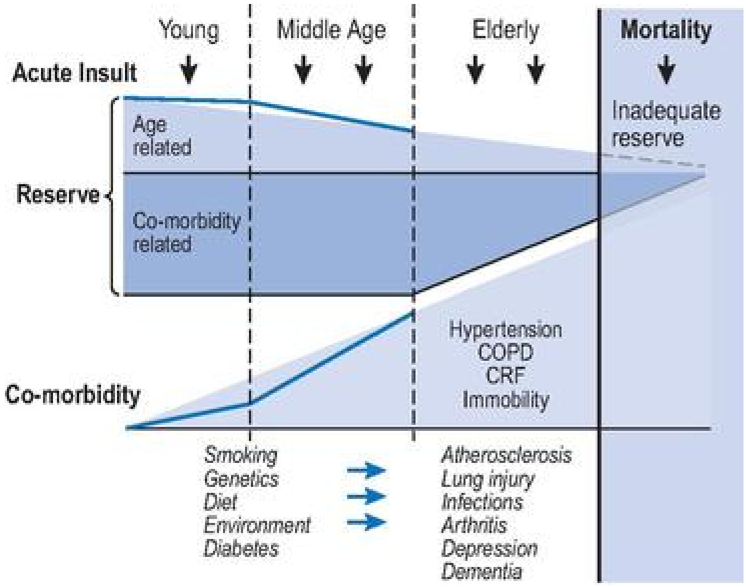
The biggest single problem in the pharmacology of the elderly is polypharmacy. Elderly patients will often be on a panoply of medications depending on their chronic health problems. Most drugs have side effects and interactions and, as the number of medications increases, so too does the likelihood of complications from their use – especially when the patient is ill. The classic example is antihypertensive drugs in the elderly causing postural hypotension. The role of polypharmacy in hospital and ICU admission has two very different mechanisms: firstly, the drugs being the source of the problem and, secondly, the impact of inadvertent discontinuation of important medications.[45] It is not a minor issue, and an important part of the assessment of the elderly should be rationalisation of medication.

Surgical Outcome

Increasing numbers of elderly patients are having progressively more complex surgery performed on them. Both operative mortality and postoperative complications are higher in the elderly and again relate to the existence of co-morbid disease, frailty and lack of physiological reserve. The fitter the patient, the less likely he/she is to experience complications, and this is true for both cardiac and noncardiac surgery.[46, 47] The National Confidential Enquiry into Patient Outcome and Death (NCEPOD) published a report in 2010 called ‘An Age Old Problem’. This report examined all deaths in patients aged 80 or over within 30 days of surgery within a 3-month period. Some key findings were that (1) routine daily input from Medicine for the Care of Older People is vital; (2) co-morbidity, frailty and disability are independent markers of risk; (3) delays in surgery are associated with a poor outcome; and (4) there is an ongoing need to provide level 2 and 3 perioperative care. Furthermore, over 90% of this population had co-morbid disease.[48] In the over-80s age group, it has been shown that medical patients had longer ICU lengths of stay and higher ICU and hospital mortality than surgical patients.[49] One study in the over-80s showed that 6-month mortality rates after ICU discharge were 30% for planned surgical patients compared with 76% for emergency surgical patients.[50] Elderly patients presenting as emergencies have been eloquently described as ‘a heterogeneous cohort of both potentially treatable patients and those who are dying’.[51] Distinguishing the treatable from the futile is difficult across all age groups, but is particularly so in the elderly where limited life expectancy is usual and severe, but unrecognised co-morbidity may exist. Committing patients and their families to emotional and physical hardship is clearly justifiable with a good outcome, but far harder to defend if the outcome is never likely to be good. The patient’s wishes or preferences should ideally be taken into account, but frequently that is not possible. This is an area of practice that has not been studied but anecdotally it is very poorly managed.

Intensive Care Unit Outcome

How the interaction between age itself, the severity of the acute illness, or the accumulated co-morbidities and declining functional status due to ageing affects ICU outcome is uncertain (Fig. 83.3). The VIP2 study, published in 2023, was a European multicentre study of 3920 patients aged 80 and above admitted to the ICU. It demonstrated that ICU admission diagnosis, SOFA score and clinical frailty score were independent predictors of 1-month mortality.[52] Acute Physiology and Chronic Health Evaluation (APACHE) scoring attributes only 7% of the outcome predictive power to age alone. Nevertheless, in some studies of ICU admissions, increasing age does appear to be independently associated with higher 30-day hospital mortality.[53] One study suggests that, of the over-80s, half will not survive the ICU, but half the survivors will be alive 2 years later.[54] In a study in Canada, one-quarter of patients aged 80 years or over who were admitted to the ICU survived and returned to baseline function at 1 year. This recovery was significantly associated with younger age, lower APACHE II score, lower Charlson co-morbidity score, lower frailty index, lower baseline physical function score, and specific admission diagnoses.[55] Intuitively, the pre-morbid functional status and presence of co-morbidities should significantly affect ICU outcomes. Even supposedly soft indicators, such as coming from a care home, were associated with higher in-hospital mortality; also the medium-term mortality at 6 months is increased if the patient is discharged to care facilities.[21] In a study of over 15,000 elderly patients compared with non-elderly ICU admissions, the elderly were more likely to have greater co-morbid illnesses and higher illness severity scores, which led to a higher ICU mortality. These patients were more likely to be discharged to either rehabilitation or long-term care.[56] Conversely, other studies have failed to find an association between outcome and pre-existing co-morbidities or functional status.[57] Elderly (aged 65 years or over) trauma patients in the ICU may have a worse outcome than previously thought, with a recent study demonstrating a 45% in-hospital mortality and only 23% of survivors being discharged home. [58]



Young
Middle Age

Dementia

The conceptual chart illustrates the relationship between aging, reserve, comorbidity, and mortality. The horizontal axis spans from young to middle age to elderly, ending at a shaded section labelled mortality. A descending line labelled acute insult shows how age-related reserve declines over time. Below that, a block labelled comorbidity-related reserve gradually rises, denoting increasing vulnerability with age. Another upward sloping line labelled comorbidity rises steadily and steepens in elderly years. Listed comorbidities include hypertension, C O P D, chronic renal failure, and immobility. The contributing risk factors below include smoking, genetics, diet, environment, and diabetes, which are shown to lead to a progression of conditions such as atherosclerosis, lung injury, infections, arthritis, depression, and dementia. The intersection of rising comorbidity and declining reserve marks the transition toward inadequate reserve and increased mortality risk.

FIG. 83.3 Factors affecting intensive care unit outcome. *COPD* , Chronic obstructive pulmonary disease; *CRF* , chronic renal failure.

Age itself is not a useful prognostic indicator and its use as a surrogate for general status is unpredictable. Nevertheless, it is possible to conclude that the outcome for elderly patients admitted to ICU is poorer than for younger patients, but that the outcome relates to the pre-morbid state (including co-morbidities and frailty), the severity of the acute illness and the presence of an underlying fatal illness, as in other populations. [54]

Quality of life is probably a more relevant factor than survival. Most patients will have a significant functional disability on ICU discharge, which may improve, although the evidence is difficult to interpret. In general, those experiencing major acute events with little pre-existing co-morbidities report a substantially lower quality of life afterwards compared with those with significant pre-existing co-morbidities; this is most probably due to relatively lower expectations in the latter group. It is a contentious area with some studies showing no real impairment in quality of life, whereas others show a significant decline in quality of life. [59]

Probably the best indicators of real outcomes for the elderly are measures, such as returning home, which has rarely been assessed but is often a very important consideration for the individual. Conti and colleagues assessed this with the results seen in Box 83.2 ; this approach is probably more relevant than mortality figures. [60] In a Canadian study, only 45% of medical and 41.6% of surgical emergency patients aged 80 or over were able to return home to live post-ICU. [49]

Box 83.2

Factors that influence elderly patients getting home from the intensive care unit

Important factors that reduce the chance of returning home

Over 75 years of age
Neoplasia
Chronic heart failure

Cirrhosis
Neurological or neurosurgical cause for admission
Trauma
Respiratory failure
Cardiology
Neurological complication
Cardiological complication
Haematological complication
Surgical complication

Less important factors that reduce the chance of returning home (except planned surgery)

Planned surgery (protective)
Visceral surgery
Chronic renal disease
Living alone

From Conti M, Friolet R, Eckert P, et al. Home return 6 months after an intensive care unit admission for elderly patients. *Acta Anaesthesiol Scand* . 2011;55:387–393, with permission.

In the future, there needs to be more focus on both physical and mental functionality as an outcome measure. Patients need to be alive have reasonable functional status, and ideally be able to return home. To achieve the best outcome for patients, multidisciplinary assessment, including the need for early rehabilitation, is crucial.

Assessment for Admission

Pre-morbid functionality and the severity of co-morbid illnesses are of paramount importance when deciding on an elderly patient's suitability for admission. This must be put in the context of the acute insult and an analysis of whether the disease process is reversible, and if the patient is salvageable. If not, then the application of intensive care is likely to impose a physical and mental burden on the patient and their family that cannot be justified by the likely negative outcome. Objective decision making is problematic, and it is worth noting that physicians may overestimate the mental and functional status of patients accepted for admission and underestimate it for those whose admission is rejected. [61] Age has little role to play in this decision other than its association with physiological decline and the acquisition of co-morbidity. Further data may enable more accurate risk prediction systems to be created, thereby enhancing informed doctor–patient dialogue on the outcome. It is also worth remembering that many elderly patients will have one form or another of advanced directives.

History

This should involve speaking to the patient or, if impossible, to their relatives to make an assessment of their previous functionality physically and mentally. Establish whether co-morbidities are present and if so, how severe. Determine whether the patient is living at home or in a nursing home and how independent he/she is. Living in a nursing home may sometimes, but not always, be a surrogate for significant functional impairment. [56] In the elderly nursing home population, anaemia, cancer, heart failure, renal failure and chronic obstructive pulmonary disease (COPD) are all related to a poor 1-year outcome. For those with previous hospital admissions, a history of ventilation is also a potentially important feature. There is a need to know the physical and mental trajectory over the last few months or years, which may indicate a significant functional decline. Details relating to the level of activity (house, room, chair or bedbound) are powerful indicators (Box 83.3).

Box 83.3

History

Where do they live – at home or in care?
Independence – how much support?
Mobility – shopping, walking

Memory – confusion, sleeping pattern
Previous hospital admissions – in particular, ventilation or chronic renal failure
Co-morbidity – respiratory, cardiology and neurology, but also arthritis and mobility
Drugs
Patient’s preferences if known

Clinical Signs

The general habitus is revealing. Posture, muscle bulk, or more often wasting, and the condition of the skin all help indicate long-term physical well-being or otherwise. Ill health is a potent cause of self-neglect, so the condition of the teeth, the lower legs and the feet are very important indicators. Peripheral oedema and infection indicate potential co-morbidities, while chest wall shape may suggest chronic airway disease. Movement and agility are less easily evaluated in acute conditions, but again some impression can be gained from the factors above. Likewise, mental acuity may be difficult to assess in an acute situation.

All of these come together to provide a picture of the level of normal functionality and the degree of co-morbid illnesses, and how they may be contributing to the acute presentation. Then the acute nature of the presentation needs to be evaluated and its reversibility taken in the context of the other problems. The patient’s preferences, either declared or previously informed, are a very important part of this assessment. Most importantly, no individual part of this should overwhelm all other considerations, and age itself is the least relevant factor.

Treatment Intensity

Elderly patients now present more frequently, have fewer co-morbidities and are more acutely unwell than in the past. They are also more likely to undergo more intensive treatment and are more likely to survive, although the intensity of their treatment may not match that offered to younger patients.[62],[63] It is vital to remember that even though an intervention is available and can be administered does not necessarily mean it should be. In addition, high-intensity treatment may be appropriate and can produce good results, but careful patient selection is key. In a study that followed more than 1 million elderly patients after a diagnosis of serious illness, half were admitted to the ICU at some point and, of these, two-thirds were still alive 6 months later.[8] However, 3% of this cohort accounted for 23% of ICU usage.

In terms of cost-effectiveness, a prospective, observational cohort study in Canada involving patients aged 80 or over demonstrated that the average cost of ICU admission per patient was CAN$31,679 ± $65,879.[64]

Expectations and Preferences

Paradoxically, the aim of treating the elderly in the ICU may be more attainable than with younger patients, as they may already have adapted to the burden of co-morbid disease and disability and have limited expectations when compared with young previously fit patients. End-of-life care increasingly occurs in a hospital setting, despite the fact that 86% of patients would prefer to die at home; therefore, the level of medical intervention that elderly patients would want is relevant. Only 16% would take life-prolonging drugs if they made them feel worse, and most would want palliation even if it shortened life. Most would not want to be put on a ventilator to gain a week of life, and the numbers were similar if it were for a month of extra life.[65] Of those octogenarians who survived the ICU, half declared they would not want ICU treatment again if it were required.[66] However, one must be careful about making assumptions in this group of patients. The SUPPORT study showed a poor understanding by physicians of patients' preferences[67] and further declared that, despite the fact that more than half of over 70-year-olds would want cardiopulmonary resuscitation (CPR), most physicians substantially underestimated this.[68]

In 1999, Singer and colleagues identified the following as being most important to patients:

- receiving adequate pain and symptom management

- avoiding inappropriate prolongation of dying
- achieving a sense of control
- relieving the burden on others
- strengthening their relationship with loved ones. [69]

End of Life

Death in the ICU is usually through some form of withdrawal. Limitation of life support is very common, as is withdrawing or withholding treatment. There is huge variation in practice between countries, not only in the decision process but also in the issuing of ‘Do Not Resuscitate’ orders, and the modes of withdrawal and withholding treatment. [70] The concept of proportionate care has been highlighted by The World Federation of Societies of Intensive and Critical Care Medicine and although we may stop treatments, we should never stop patient care. [71]

Patient preferences are very important, as is physician recognition of medical futility. The key to this area of management is (1) a clear view of what the ICU is intended to provide; (2) an understanding of whether the goals are achievable; and (3) acceptance that subjecting a patient and their family to the unpleasant rigours of the ICU in the sure knowledge that it will achieve no useful outcome is unacceptable. These determinations must be made objectively.

COVID-19 in the elderly

Older adults are more likely to have severe COVID-19 infection and have higher mortality. More than 80% of the global COVID-19-related deaths between 2020 and 2021 occurred in people aged 60 or above. [72] In the United States, the 2020 death rate for those aged 85 and over was 2.8 times higher than the rate for 75–84 years and 7 times higher than for the age group 65–74 years. [73] The impact of vaccination on the risk of mortality in elderly patients remains unclear. Decision making regarding ICU admission, escalation and end-of-life care for elderly patients with COVID-19 should be performed carefully, taking into account all the issues discussed in this chapter, such as co-morbid disease, frailty and disability.

Conclusion

The APACHE score demonstrates that most predictive power for the outcome is derived from the acute physiological condition; a much smaller component was the admission disease (13.6%) and age (approximately 7%). [53] The nature of the acute condition and the severity of co-morbid disease play a far greater part than the known physiological changes that accompany ageing, and thus absolute age itself. The reversibility of these factors should guide management, and this approach is the same for any patient of any age. It is more likely that an older patient will have advance directives and will have already voiced their personal preferences.

A simplistic view is that intensive care entails reversing an acute episode with the intention of returning the patient to the position they were in before that episode, or close to it. The majority of treatment is supportive and provides the physiological reserve that the elderly patient is likely to have lost until it can be regained. Those with less reserve will need more support. The patient will invariably need a certain amount of physical reserve to meet the challenges of the treatment and recovery. The decision to use the ICU requires acknowledgement that the ICU has negative as well as positive aspects and that it can be a very unpleasant experience with far-reaching sequelae, both physical and psychological, for patients and relatives. Justification is provided by a good outcome, so it is implicit that the opinion at the time of admission is that full recovery is possible or indeed probable. As in every other population, appropriate use of intensive care can produce impressive results, but inappropriate use can be disastrous for the patient and their family. Age itself is not a contraindication.

Obesity

Rob Bevan

Definitions

The term ‘obesity’ has developed from quantitative and qualitative medical definitions into the social and political narrative, at times with pejorative connotations for individuals and groups.

The World Health Organisation (WHO) defines obesity as an abnormal or excessive fat accumulation that presents a risk to health. [1] The concept of ‘obesity as a disease’ (rather than representing ‘good living’) has only arisen over the last century: In the early 18th century, insurance data linking ‘body frame’ to death rates introduced the notion of an ‘ideal’ weight for a given height. The recognition in the 1830s that the ratio of a person’s weight in kilograms to the square of their height (in metres) provided a more pragmatic tool, and eventually led to the term Body Mass Index (BMI). [2] The WHO incorporated BMI to define people into weight categories. This has been further refined to describe Class I-III Obesity (Table 84.1). [3] For children, obesity is a BMI >2 standard deviations above the WHO growth reference median. [1]

Table 84.1

WHO BMI: Classification of obesity

CATEGORY	BMI (kg/m^2)
Underweight	<18.5
Overweight	25–29.9
Class I obesity (moderate)	30–34.5
Class II obesity (severe)	35–39.9
Class-III obesity (very severe)	40 or greater

Adult categories by BMI. Paediatric obesity = BMI >2 standard deviations above the WHO reference median.

BMI does not measure body fat. Extrapolating a person's adipose tissue fraction from an index developed from a narrow, historic, 'Anglo-Saxon' population sample has been shown to be problematic: Age, gender, ethnicity, and muscle mass all confound the relationship.[2-5]

Demographics

According to the WHO, the worldwide prevalence of obesity tripled between 1975 and 2016.[1] In the UK, Australia, Aotearoa New Zealand and the United States (US), between two-thirds and three-quarters of adults are classified as overweight or obese.[6]

The costs to society are substantial: By 2005, 21% of the US National Health expenditure was on obesity-related conditions.[7] Even more startling is the estimation that between 2010 and 2030, 2–6 and 25–48 million quality-adjusted life-years would be lost in the UK and US respectively to obesity-related disease.[8]

The obesity epidemic is reflected in ICU admission trends. By 2020, 68% of adult ICU admissions in Australia and Aotearoa New Zealand were overweight or obese, whilst 16% were classified as having Class II obesity and above.[9]

There is little sign of this epidemic abating. The individual-focused solution of ‘eat healthy food and exercise more’ is oversimplified: In reality, the complex interplay of social determinants of health, government policy and regulation exist in tension with the interests and influence of a powerful global food industry.

Pathophysiology

The fundamental driver of obesity is energy intake (metabolised food) in excess of energy expenditure, with fat stored as triglycerides within modified fibroblasts called adipocytes.[10] Adipocytes can proliferate at any stage of life; an extremely obese person may have as many as four times as many adipocytes, each containing twice as much lipid as a lean person.[10] However, when the adipocyte storage capacity is exceeded, lipid storage within muscle and liver occurs, promoting insulin resistance and direct organ-specific lipo-toxicity.[11] Adipose tissue is metabolically active, releasing pro-inflammatory mediators into the vasculature.[12]

Monogenic and polygenic causes of obesity have been described – the former being rare, but the latter attributable to over 220 variants affecting multiple digestive and metabolic processes.[13,14]

Despite our emerging appreciation of genetic risk factors, the pace of change in the prevalence points to a dominant environmental component of obesity. The increasing availability of cheap, calorie-rich food and drink, consumed in ever-increasing portion sizes is likely driving excess energy intake.[15,16] In comparison, the transition to more sedentary jobs over the last few decades is thought to represent only modestly decreased caloric expenditure.[17]

When obesity does manifest, the net effect is a whole-body alteration in metabolism, endocrine, and reproductive function, which accompany the organ-specific complications described below.[18]

In summary, not all people exposed to these factors become obese. Whilst some people are stubbornly lean, others encounter significant struggles with preventing weight gain. This lends credibility to the notion that obesity (like countless other medical conditions) results from the complex interplay of a person’s environment on their genetic predisposition, overlaid by confounding medical conditions.

Organ Systems

Each organ system is affected by obesity – either from direct alteration or indirectly from associated medical co-morbidities. Body fat distribution may determine the extent to which a particular organ system is affected – for example central/abdominal accumulation will affect breathing more than that around the hips. [19] A summary of obesity effects on body systems is presented in (Table 84.2) with selected ICU-specific clinical implications discussed under ‘Clinical Considerations’.

Table 84.2

Effects of obesity on organ system physiology. Overview of obesity changes by body systems

Obesity Changes (By System)	Possible Effects
Cardio-Respiratory	
↑Adipose tissue in face/pharynx	↓Upper airway volume
	Obstructive sleep apnoea→hypertension
↑Upper airway collapsibility	↑Upper airway resistance
↑Fat accumulation in chest/abdominal wall	↓Compliance of respiratory system
	Lower airway collapse
	Airway hyper-responsiveness
	V/Q mismatch → hypoxaemia
↓Respiratory drive from the CNS	Hypoventilation
↑Blood volume	↑preload→ RA/RV dilation, remodelling
↑Cardiac output	↑filling pressures→ LV/RVH→ heart failure
Atrial/Ventricular remodelling	Atrial fibrillation
	Sudden cardiac death
Vascular Endothelial dysfunction	Coronary artery disease
	Venous stasis→ chronic ulceration
Renal	

Obesity Changes (By System)	Possible Effects
↑ Glomerular blood flow	Glomerulosclerosis
Lipid deposition	Inflammation
Chronic RAS activation ↑CVD risk factors	Hypertensive renal disease Chronic kidney disease
Hepatic/Metabolic	
↑FFAs and TGs	Insulin resistance, MAFLD
↑ Body fat and Lean mass stores	Inflammation, metabolic dysregulation

Explanatory notes are in the text. NB: ↑↓→represent ‘increase’, ‘decrease’ and ‘may lead to’ respectively.

Respiratory

Anatomical and physiological alterations to the upper airway, chest wall and central nervous system result in clinically relevant changes in airway anatomy, pulmonary function, breathing, oxygenation and ventilation.[20, 21]

Upper airway collapsibility is due to the reduction in caudal tracheal traction from the compressive effect of the abdominal wall and visceral fat.[21] Restricted outward and downward movement of the ribs and diaphragm increase the intra-pleural and intra-abdominal pressures, resulting in reduced compliance and increased resistance. The overall effect is an increase in the minute ventilation (via tachypnoea) and work of breathing.[19, 22]

Obesity results in a significant reduction in functional residual capacity (FRC) and expiratory reserve volume (ERV) in adults, with the FRC being proportional to the degree of obesity. The FEV_1/FVC ratio is increased. The opposite is observed in children, with an increase in FEV_1 and FVC due to airway dysanapsis (disproportionate growth between lung and airways).[23]

Obesity hypoventilation syndrome (OHS) is defined in obese patients with daytime hypoventilation ($PaCO_2$ of 45 mm Hg (6 kPa) or greater and PaO_2 of 70 mm Hg (9.3 kPa) or less at sea level) and sleep-disordered breathing. Most OHS patients have concomitant obstructive sleep apnoea (OSA).[24]

Cardiovascular

Obesity (visceral obesity in particular) contributes directly to the risk factors for atheromatous coronary artery disease and heart failure, including dyslipidaemia, type 2 diabetes, hypertension, and kidney disease. Obesity also leads to the development of heart failure and arrhythmias with mortality independent of other cardiovascular risk factors.[12, 25]

Increased blood volume leads to chronically raised preload, resulting eventually in dilation of the right atrium and ventricle (RA, RV). RV afterload is increased – especially with OSA/OHS-induced pulmonary hypertension. Cardiac output is raised, predominantly from an increase in stroke volume rather than heart rate. Left ventricular (LV) afterload is raised due to hypertension and reduced vascular compliance.[20, 25]

The pressure changes result in ventricular hypertrophy. The gradual accumulation of myocardial fat, with subsequent inflammation and fibrosis can lead to an elevated LV filling pressure and impaired relaxation. This results in heart failure with preserved ejection fraction. Failure of the LV from dilation (and/or infarction) can lead to heart failure with reduced ejection fraction. Both forms of LV failure manifest as a significant decrease in exercise capacity in obese individuals.[12, 22, 25] RV hypertrophy, dilation, dysfunction and eventually failure can also develop.

Obesity is a major cause of atrial fibrillation, with atrial remodelling, abnormal atrial conduction, and impaired contractility all contributing. Sudden cardiac death from ventricular arrhythmia is due to epicardial adipose tissue, and fibrosis.[12, 20]

Finally, endothelial dysfunction occurs because of systemic inflammation, with enhanced atherogenesis. The presence of additional atherogenic risk factors will accelerate the process. [25] Chronic leg ulceration, infection and poor wound healing are a frequent complication of the right heart failure seen in severe obesity.

Renal

Obesity is an independent risk factor for the development of chronic kidney disease (CKD). [26] Lipid deposition, inflammation, hyper-filtration, and chronic activation of the renin-angiotensin-aldosterone system (RAS) have all been implicated. [27]

Acute kidney injury (AKI) is complicated by the fact that weight-based definitions and traditional equations may over-estimate AKI in obese patients, clouding the interpretation of the literature. [20], [28] Notwithstanding, using definitions based on creatinine rise, and focusing on the more valid GFR equations for this population demonstrates that obesity appears to be an independent risk factor for AKI in patients admitted to the ICU. [29]

Metabolic/Liver

Adipose tissue is in effect an endocrine organ, secreting a host of ‘adipokines’ which modulate metabolic processes. This affects energy homeostasis and metabolism, immune response and reproduction. Obesity reduces the disposal of glucose into adipose tissue, and increases lipolysis, with elevated levels of circulating free fatty acids (FFAs) and triglycerides (TGs). The resultant ‘metabolic syndrome’ of insulin resistance, dyslipidaemia, hypertension and accelerated atheroma is well described. [18]

For the liver, the term ‘metabolic-associated fatty liver disease’ (MAFLD) has emerged to describe the adverse hepatic effects of metabolic dysregulation and steatosis. This definition replaces non-alcholic fatty liver disease (NAFLD) and pragmatically accounts for other risk factors (such as alcohol or chronic viral infection). [30] The mechanism traditionally postulated a ‘two-hit’ phenomenon, with lipid accumulation and insulin resistance triggering inflammation and fibrosis. [31]

Clinical Considerations

An overview of the clinical considerations is presented in Table 84.2 .

Airway Management

Obesity alters the anatomy of the face, neck and pharynx resulting in difficulties in mask fit, airway patency, and the *perception* of intubation difficulty. [20] The relationship between obesity and airway difficulty is not straightforward. The following considerations guide the rapid sequence induction (RSI) of an obese patient in the ICU:

- **Anatomy** : BMI alone is not a strong predictor of face mask ventilation and intubating difficulty, however the presence of a neck circumference of 42 cm or greater, and/or a Mallampati score of 3 or greater are. [32, 33]
- **Positioning** : 'Ramping' the patient so that the tragus is level with the sternal notch is recommended to facilitate patient comfort, non-invasive ventilation (if used), bag-mask ventilation, and laryngoscopy. [33, 34]
- **Pre-oxygenation** : Obesity brings the particular risk of rapid and severe desaturation during induction of anaesthesia. Combining high-flow-nasal-oxygen (HFNO) with the traditional facemask pre-oxygenation appears to be a pragmatic way to incorporate 'apnoeic oxygenation' and reduce hypoxaemia by maintaining the FRC. [35]
- **Intubating equipment** : There are conflicting data regarding optimal laryngoscopy techniques and equipment for obese patients in the ICU setting. The evidence supporting the increased safety profile of video-laryngoscopy (VL) compared to direct-laryngoscopy (DL) has been published by Cochrane, [36] albeit with 8/21 studies in an ICU setting. The DEVICE study demonstrated a higher first-pass success with VL, although most operators reported <100 intubations and low DL experience. [37] Within the ICU, it is unclear whether a hyper-angulated VL blade offers any benefit over DL. [32]

Tracheostomy (surgical and percutaneous) has traditionally been associated with increased complications for obese patients.[20] It appears that careful patient preparation, video endoscopy, ultrasound and ‘adjustable flange’ tubes have all contributed to the increase in safety in this group.[38,39]

Mechanical Ventilation and Weaning

For the provision of invasive ventilation, the following should be especially considered:

- **‘Adequate’ positive end-expiratory pressure (PEEP**): The reduction in end-expiratory lung volume (EELV) in awake obese patients is magnified by the sedation and muscle-relaxation required for induction of anaesthesia. In this context, PEEP is used to prevent alveolar de-recruitment. Whilst a PEEP of 5 cmH_2O may be sufficient in non-obese patients without acute lung injury, this level of PEEP is inadequate to prevent an increase in atelectasis and hypoxia.[40] PEEP offsets the risk of small airway collapse and gas-trapping during early expiration, with as much as 16 cmH_2O required to prevent alveolar decruitment.[20] However, this needs to be balanced by the patient’s ability to tolerate the adverse haemodynamic effects of the resultant reduction in venous return.
- **‘ Appropriate’ Tidal volume (V_T)** : Setting V_T using ideal body weight (IBW) rather than actual body weight (ABW) to prevent ventilator-associated lung injury is well established.[22] However, even this accommodation may lead to over-estimations in the context of reduced EELV.[41]

Liberating an obese individual successfully from mechanical ventilation may be challenging. The most important factors to consider are the prolonged residual effects of sedation and analgesia, the prevention of de-recruitment with PEEP, and the prevention of hypercarbic respiratory failure post-extubation using HFNO or NIV. The choice of which of these is ‘best’ should be guided by patient factors: Whilst HFNO works for most, individuals with OSA and moderate hypercarbia ($PaCO_2$ 55 mm Hg or above), or a history of hypercarbic respiratory failure *probably* benefit from continuous positive airway pressure ventilation (CPAP) following extubation.[41, 42]

Rescue Therapies

Prone positioning is a safe and effective rescue therapy for refractory hypoxic respiratory failure due to acute respiratory distress syndrome (ARDS).[43] Obese patients benefit the most from ‘proning’,[44] although in practice the acceptable ‘weight limit’ will be iterative and nuanced for each ICU.

For veno-venous extracorporeal membrane oxygenation (ECMO), there is no ‘cut-off’ weight after which the therapy is impossible. Data obtained during the COVID pandemic demonstrated that BMI carries a linear increased risk of ECMO complications and mortality.[45] Whilst using BMI alone as a prognosis-based exclusion criterion for ECMO is challenged,[46] transport equipment weight/girth limits and underlying cardiac function will likely determine the practicality and utility of ECMO respectively for severely obese patients.

Cardiovascular Assessment and Support

Clinical assessment of volume status, non-invasive blood pressure, haemodynamic monitoring, electro- and echo-cardiography are all more challenging (but not insurmountable) in obese individuals.[12, 22] A carefully sized non-invasive blood pressure (NIBP) cuff should enable accurate readings, however unstable patients require invasive blood pressure monitoring.[47]

From the few studies available, fluid dosing on ideal versus ABW has not been shown to alter outcomes in patients with sepsis.[48] Vasoactive agents used in ICU should ideally be charted based on ideal body weight (IBW), or as a non-weight-based dose to consistently describe levels of haemodynamic support. [49]

Obtaining adequate peripheral and central vascular access is more challenging in obese individuals, although bedside ultrasound as a standard of care has mitigated this to some extent. Objectively assessing and tracking cardiac output using non-invasive cardiac output monitoring devices is less reliable in obese patients. [47] Transesophageal echocardiography may mitigate this.

Renal support

Despite sparse data, it appears possible to provide continuous and intermittent renal replacement therapy (RRT) in the ICU setting to patients at the extremes of obesity. Vascular access should avoid the femoral route in obese patients to promote circuit life and reduce catheter-related bloodstream infections. [50] One notable case report details the prolonged ICU stay of a *466 kg* individual, with RRT ongoing over many weeks. [51] There is minimal guidance on whether ideal or ABW should guide RRT prescription. [52]

Nutritional Support

The provision of nutritional support to critically ill patients is a source of controversy in an area richer in guidelines than evidence. Whilst a comprehensive description of providing nutrition to critically ill patients is outside the scope of this chapter, there are specific challenges for patients with obesity: [53]

Assessment of nutritional status: Obese individuals may have underlying malnutrition, with symptoms and signs of macro and micro-nutrient deficiencies. Standard tools for assessment are not validated at the extremes of weight.

Estimation of energy requirements is ideally guided by the resting energy expenditure (REE) measured by indirect calorimetry (IC). Failing this, energy requirements can be estimated using an ‘adjusted body weight’ (AjBW) formula. [54] One frequently cited formula for $\mathrm{AjBW} = (\mathrm{ABW} - \mathrm{IBW}) \times 0.25 + \mathrm{IBW}$]. [55]

Protein requirements and ‘sarcopenic obesity’: Reduced muscle mass (sarcopenia) in conjunction with obesity is an increasingly recognised phenomenon in ICU. [56] So-called ‘sarcopenic obesity’ manifests as a rapid reduction in muscle mass via enhanced catabolism despite ‘standard’ ICU nutritional support. [56]

The nutritional guidelines advocate (where possible) an enteral feeding approach using a hypocaloric, high-protein strategy. Energy targets should be approximately 25 kCal/kg/day of AjBW, or 80%–100% REE. [47] In the absence of accurate lean body mass data, a recommended strategy for addressing the increased protein needs of these patients is to adjust protein intake to at least 1.3 g/kg AjBW/day. [55] Frequent re-assessment of macro and micro-nutrient status and adjustment of feeding goals over the course of the illness is recommended. [53]

Obstetric care

Pregnant women who are obese have higher incidences of hypertension, preeclampsia, gestational diabetes, and elective caesarean rates. Almost half of women with Class-III obesity progress to caesarean, most under regional anaesthesia. [57] This population has a significantly increased risk of hypotension and requirement for vasopressors. [58]

Pharmacotherapy

Obesity has significant effects on the pharmacokinetics of agents used in ICU, with distribution, protein binding, metabolism and clearance all potentially affected. [22]

Few of the drugs frequently used in ICU have data related to dosing in obesity, and those that do are rarely derived from patient-centred outcomes or an ICU/critical illness setting. [20, 59] Pragmatically, care should be taken when drugs have weight-based dosing (low molecular weight heparins [LMWH]), are widely distributed in adipose tissue (propofol and benzodiazepines), or possess a narrow therapeutic window (phenytoin, LMWH and digoxin). [20]

Obesity is inevitably superimposed on acute illness and underlying co-morbidities with variable drug effects in an individual patient. Recommended principles for dosing common ICU drugs are summarised in Table 84.3 . Close liaison with an ICU clinical pharmacist where possible is highly recommended.

Table 84.3

Considerations for dosing medications for Obese patients in ICU

Drug Class	Pharmacological Factors in Obesity	Weight/Strategy
Analgesics: Opioids Paracetamol Ketamine	↑ Vd, ↓ metabolite clearance Liver injury risk if dose ↑ by weight ↑ Vd likely trumps ↑clearance	AjBW Standard dosing IBW
Sedatives: Propofol Dexmedetomidine Midazolam	↑Vd offset by ↓clearance and AE's Inter-patient variability, ↓clearance Clearance not impacted by obesity	IBW or AjBW
Antipsychotics: Haloperidol, Quetiapine	↑Vd offset by ↑QTc concerns	Standard dosing
Vasoactive agents: Noradrenaline, Dopamine Adrenaline	Low Vd, rapid clearance	Standard dosing
Corticosteroids: Hydrocortisone Methylprednisolone	For shock Various indications	Standard dosing AjBW
Stress-ulcer prophylaxis: PPIs, H2RB's	Minimal pharmacodynamic change	Standard dosing

Drug Class	**Pharmacological Factors in Obesity**	**Weight/Strategy**
VTE prophylaxis: LMWH UFH	Frequently sub-therapeutic at standard doses	1.5 × standard dosing reasonable [a]
Antimicrobials: Vancomycin Gentamycin	↑renal clearance if ↑GFR at baseline or converse in AKI/CKD	Patient-specific dosing calculations required

Principles and suggested weight-based dosing strategies for common drug classes used in ICU [20-Shashaty, 47-Erstad, 57-Erstad].

AE's , Adverse effects; *AKI* , acute kidney injury; *CKD* , chronic kidney disease; *GFR* , glomerular filtration rate; *H2RB* , histamine receptor blocker; *I or Aj BW* , ideal/adjusted body weight; *LMWH* , low molecular weight heparin; *PPI* , proton pump inhibitor; *QTc* , corrected QT interval [prolonged on ECG]; *UFH* , unfractionated heparin.

([a] in amount or frequency of administration); *Vd* , volume of distribution; *VTE* , venous thromboembolism.

---

[a] May be anti-Xa guided.

Thromboembolic Complications

Venous stasis, reduced mobility, systemic inflammation, and endothelial dysfunction all combine to significantly increase the risk of venous thromboembolism (VTE) in critically ill obese patients. Obesity complicates the diagnosis and treatment of VTE in the ICU. [47, 60] Diagnosis is hampered by unreliable clinical signs and sonographic views. Despite CT pulmonary angiography (CTPA) images being suboptimal in some obese individuals, the literature suggests it still performs well in these patients. [60]

Special Considerations

Unit Design and Staffing

As patients (and their families) become larger, our ICUs must adapt. The safety and adequacy of beds, bed spaces, bathrooms, gowns, mobility and transfer aids, chairs and visiting areas all require consideration. [61] The nursing workload for obese patients is considerable, with workplace injuries carrying huge personal and resource implications. Devices and training for ‘safe patient handling’ combined with adequate staffing are essential. [62]

Perioperative planning

Perioperative care is an increasingly interdisciplinary field, and obese patients warrant special consideration. [63] There has been an increased focus on pre-operative risk stratification, intra-operative non-opioid options, and post-operative care pathways (which may increasingly involve ICU). There is a perception that increased monitoring and disposition of these patients to critical care is going to improve outcomes. [63] An interprofessional approach is going to be required to provide evidence-based care that aligns resources with need of the growing numbers of perioperative patients who are obese.

Imaging

Even accounting for the challenges of intra-hospital transport, there is a challenge in providing high-quality imaging for obese patients: CT and MRI table weight limits have increased to accommodate heavier patients, but a fixed gantry diameter means patient girth rather than weight determines available modalities. [60], [64]

Bias

There is an increasing recognition of conscious and unconscious bias in health care. Stigmatisation of overweight individuals may be a significant barrier to them accessing and receiving appropriate care.[62, 64-66] Clinicians need to be aware of individual and systemic biases, and the effect that pejorative language may have on patients and families. It is important that health jurisdictions appreciate the relationship between adequate staffing, equipment provision, and how healthcare teams respond to the increased burden of nursing morbidly obese patients.[67] The (false) perception that obese individuals are entirely to blame for their predicament is not uncommon.[47, 64] It is incumbent upon us all to ensure that patients and their families feel welcome and valued in the ICU.

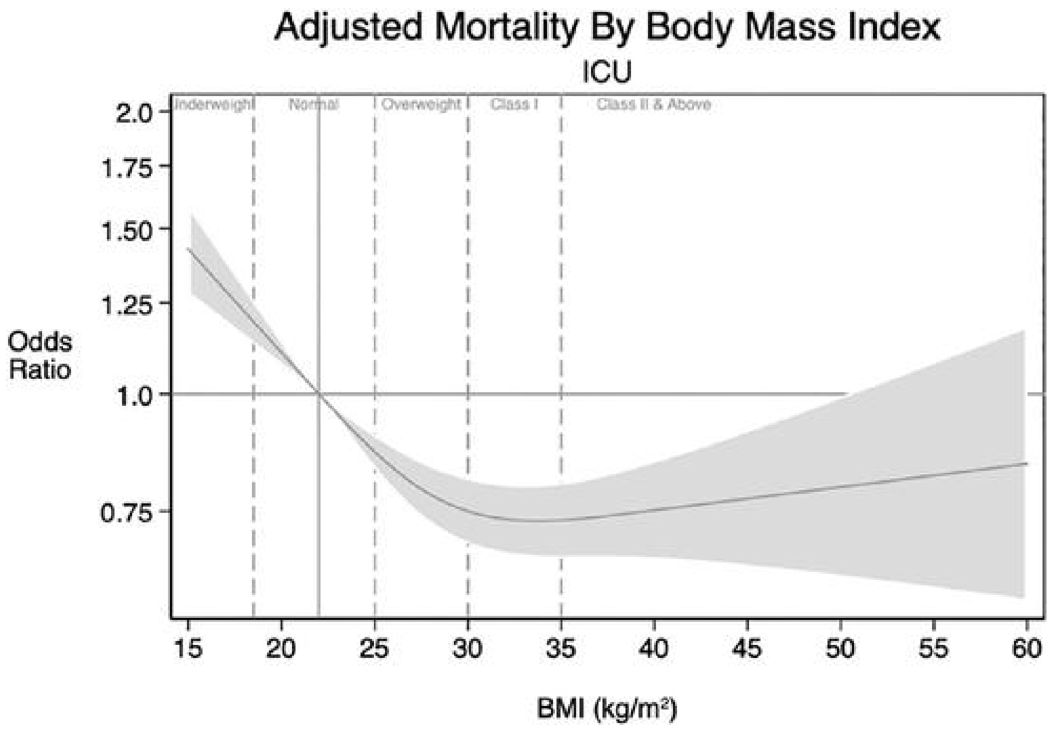
Patient Outcomes: The Obesity Paradox

A meta-analysis of global studies of over 10.5 million people examined the effect of BMI on all-cause mortality. The result was a J-shaped curve, with a higher mortality in those with a BMI between 15 and 20 kg/m, and lowest for BMI 20–25 kg/m^2. For a BMI over 25 kg/m^2, mortality increased approximately log-linearly.[68]

The harmful effects of increased body fat on population mortality and morbidity are countered by the consistent finding that obesity appears to convey a survival advantage among patients with chronic diseases are studied.[69] This is known as the ‘obesity paradox’.

ICU studies have traditionally focused on cohorts of critically ill patients with distinct processes (e.g. sepsis, pneumonia or ARDS), with the lowest mortality consistently reported in patients with Class I obesity.[70, 71, 72]

A large cohort of adult ICU patients in Australia and New Zealand provides a clear and consistent signal; apart from those admitted to ICU due to cardiac disease, cardiac surgery or trauma, adjusted mortality appears to be lowest for patients with Class I obesity. Furthermore, increasing obesity does not match the risk of being underweight (Fig. 84.1).[9]



The graph titled Adjusted Mortality by Body Mass Index with a subtitle I C U. The horizontal axis represents B M I in kilograms per square meter, ranging from 15 to 60. The vertical axis shows the odds ratio from 0.5 to 2.0. A curved line represents adjusted mortality risk, with a shaded region surrounding it to show confidence intervals. The graph shows that adjusted mortality risk is highest at low B M I levels, particularly below 20, and lowest between B M I values of 27 to 35. Beyond a B M I of approximately 40, the curve rises again, showing an increased mortality risk with higher B M I. Vertical dashed lines divide the graph into categories labelled underweight, normal, overweight, class one, and class two and above. A horizontal line at an odds ratio of 1.0 serves as a reference.

FIG. 84.1 Adjusted mortality by BMI for all recorded patients in ANZ ICU between 2010 and 2018. Note: Mortality (95% confidence interval) adjusted for illness severity, hospital type, admission year, region, gender and diagnostic category. *ANZ* , Australia and New Zealand; *BMI* , body mass index. From Secombe P, Woodman R, Chan S, Pilcher D, van Haren F. Epidemiology and outcomes of obese critically ill patients in Australia and New Zealand. *Crit Care Resusc* . 2020;22(1):35-44. Supplementary figure 10.

There is controversy around whether the ‘obesity paradox’ represents a true protective effect of moderately increased body fat or an illusory confluence of statistical error. The paradox may simply represent an interaction of four statistical biases: Misclassification bias (BMI being a poor surrogate for high body fat), confounding (obesity and mortality have shared-cause, not controlled-for), collider-stratification bias (obesity and another inadvertently controlled-for risk factor influence mortality), or patient selection bias (e.g. ‘fitter’ obese patients are accepted for ICU admission).[9,69,73]

Alternatively, the paradox may be a real effect with three contributors:[47]

- The ‘Class I obesity’ group is less likely to be malnourished than the underweight.
- Fat stores may act as a fuel source unavailable to cachectic patients.
- The endocrine functions of fat tissue may attenuate the inflammatory response via immunomodulation.

Notwithstanding, the ‘paradox’ persists despite adjustment for the (known) confounders.[9]

Future Directions

Bariatric surgery is an established efficacious treatment for obesity.[74] The challenge is applying this in an equitable way to those who stand to benefit most. Medical treatments are also emerging; Glucagon-like peptide 1 receptor (GLP1R) agonists have numerous outcome benefits, although concerns about pancreatitis and cancer may prove important for ICU clinicians to be aware of despite reassuring meta-analysis data.[75,76]

Conclusion

Obesity is a growing phenomenon globally, with clearly established health risks for those affected. It is essential to remember that there are heavy people who are healthy, and that ethnicity is an important determinant of this.

Obesity complicates the diagnosis, monitoring and management of the critically ill. It has significant implications for ICU capacity, infrastructure and staffing. Societal and healthcare staff biases may affect our perceptions of the benefit of admitting critically ill patients with obesity to the ICU. The better-than-expected outcomes for individuals with high BMI who are admitted to our ICUs warrants further research, and a nuanced approach to individual treatment decisions.

It seems intuitive that there is a difference between the outcomes of those who present with critical illness and happen to be obese, versus those who present with end-stage organ failure because they are obese. Maybe it is the former group who are already selected for admission to ICU over the latter, contributing to the apparent obesity paradox. In conclusion, as in the case of age, obesity by itself should not be seen as a contraindication for ICU admission and the provision of organ support when a patient-centred outcome benefit may exist.

The immunocompromised host

Alex Padiglione and Steven A. McGloughlin

Diverse host defence mechanisms protect the body from a great variety of microorganisms and also play a role in protecting us from cancer. There is a coordinated immunological response to infection, involving both cellular and humoral components. The immune system can be defective in many ways, leading to an increased propensity to infections, and sometimes cancer. However, the response also needs to be controlled to avoid inappropriate and excessive activation, such as when excessive systemic activation occurs in sepsis and septic shock.

Innate Immunity

The innate immune system is the first line of defence against many microorganisms and tissue damage, providing immediate but non-specific responses that do not require prior exposure to antigens from those microorganisms. There are multiple cell types that contribute to the innate immune response with highly specialised functions including granulocytes and macrophages that mediate phagocytosis, natural killer cells, plasmacytoid dendritic cells, innate lymphoid cells, NK cells as well as macrophages and granulocytes. The major difference to the adaptive immune response is that cells involved in innate immunity lack unique antigen-specific receptors. The innate system is stimulated by receptors such as toll-like receptors that detect components of molecules from damaged tissues or from pathogens. The innate immune system also responds to cytokines as mediators and it also has an important role in antigen presentation to stimulate the longer-lasting adaptive immune. Understanding of the innate immune system, as with all parts of the immune system is rapidly evolving. [1]

Acute-Phase Reaction

The acute-phase reaction is a response of the haematopoietic and hepatic systems, involving many plasma proteins and cellular components of the blood. There are over 200 acute-phase proteins that have been discovered that are produced by hepatocytes predominately, although in some cases they are produced by peripheral tissues. It occurs within hours of acute physical stress or infection. Most of the involved proteins are inflammatory mediators or inhibitors of transport proteins. Fibrinogen, the bulk protein of the coagulation system, is one of the plasma proteins to show the greatest rise in the acute-phase reaction and is responsible for the elevation in the erythrocyte sedimentation rate. Decreases in haemoglobin, serum iron and albumin can also occur. The fall in albumin is due to redistribution and decreased synthesis and generally does not require supplementation. Potential functions of proteins produced in the acute-phase reaction include recognition of microbial moieties and damaged cells or tissues.

The Adaptive Immune System

In contrast to the innate immune system, adaptive immune responses demonstrate specificity, memory, amplification and diversity. This specificity (immune response against a particular antigen) and memory (prompt response on subsequent exposures) is mediated by antigen receptors on the surface of lymphocytes. Amplification and diversity of immune responses are regulated by cytokines, which are secreted by lymphocytes and other cells, and through the effects of various lymphocyte surface molecules, including adhesion molecules and co-stimulatory molecules. Cytokines have various activities, the most important of which are cell activation (e.g. interferon gamma [IFN-γ]), regulation of immune responses (e.g. interleukin [IL]-10) and pro-inflammatory effects (e.g. tumour necrosis factor [TNF] and lymphotoxins).

Antigen Presentation and the Role of T and B Lymphocytes

The adaptive immune response is initiated by the processing and presentation of fragments of a microorganism in a form that makes them antigenic to lymphocytes. Major histocompatibility complex (MHC) class I (human leucocyte antigen [HLA]-A, B, C) and class II (HLA-DR, DP, DQ) molecules are the major cell-surface antigen presentation molecules, and determine the nature of the subsequent response against the antigen.

Class I MHC molecules are present on most nucleated cells, and present processed peptides (such as fragments of viruses) to the T-cell receptor (TcR) of CD8+ (cytotoxic) T lymphocytes. Activated CD8+ T cells have a cytotoxic effect on the presenting cell, resulting in the death of the cell and inhibition of viral replication.

Class II MHC molecules are found on macrophages and monocytes (where they present fragments of phagocytosed microorganisms to TcRs on CD4+ [helper] T cells) and B cells (where the antigen is bound to specific surface immunoglobulins, the B-cell antigen receptor).

Activation of CD4+ T cells by these exogenous antigens results in the expression of cell-surface molecules and secretion of cytokines with immunoregulatory effects. These immunoregulatory molecules augment the functions of many other cells, including B cells, T cells and macrophages (T-cell help). CD4+ T-cell activation may also elicit macrophage activation (critically dependent on the production of IFN-γ) to assist in the killing of the microorganism.

Proliferating B cells differentiate into plasma cells, which secrete immunoglobulins with antibody activity against the initiating antigen, or into memory B cells, which live for a long time and rapidly respond to re-exposure to an antigen.

Immunoglobulins

Immunoglobulins are heterodimeric proteins composed of two heavy and two light chains, with two functional areas – a variable domain that binds antigens and a constant domain. There are five main classes of heavy chain

C domains – IgM, IgG, IgA, IgD and IgE. IgG can be split into four subclasses – IgG1, IgG2, IgG3 and IgG4. IgA can be split into IgA1 and IgA2, all the different classes have different functions[2] (see Table 85.1).

Table 85.1

Immunoglobulin isotypes

IMMUNOGLOBULIN	TYPES	CHARACTERISTICS
IgM	1	First immunoglobulin expressed B during B-cell development and associated with primary immune response and can be used to diagnose acute exposure to a pathogen Important opsonin Activates complement and works as a bacterial agglutinator
IgA	2	Higher levels than IgM but considerably lower than IgG in serum but much higher levels at mucosal surfaces and secretions Critical at protecting mucosal surfaces from toxins, virus and bacteria IgA_1 and IgA_2 Produced at secretory surfaces, such as the mucosa of the gut and respiratory tract, and also in the breast, where it is a major constituent of colostrum and provides secretory antibody to the gut of the neonate
IgE	1	Produced at mucosal surfaces and potent immunoglobulin Important part of the immune response against parasitic infections

IMMUNOGLOBULIN	TYPES	CHARACTERISTICS
		Associated with hypersensitivity and allergic reactions
IgD	1	Found at low levels in the serum with a short half-life Function is unclear of circulating IgD Membrane-bound IgD proposed to regulate B-cell fate during activation
IgG	4	Predominant isotype found in the body Longest serum half-life Numbered in order of the serum levels in the body. IgG1>IgG2>IgG3>IgG4 IgG$_1$ and IgG$_3$: Important opsonin, particularly effective at activating complement and binding to Fc receptors on phagocytic cells IgG$_2$: mainly active against polysaccharide antigens, such as those present in bacterial cell walls IgG$_4$: functions remain uncertain

Secondary Antibody Function

Antibodies act through one of several secondary effector mechanisms. Antibodies complexed with antigens can activate the complement system through the classical pathway, resulting in the generation of biologically active molecules, such as C3b, which is an important opsonin, and the activation of the membrane attack complex (MAC), which directly lyses bacterial cell walls.

Antibodies of the IgM, IgG$_1$ and IgG$_3$ isotypes are also important opsonins. These molecules, when bound to the surface of a microorganism, enhance binding to immune cells and facilitate their phagocytosis. These effects of complement and antibody are mediated through complement receptors (CRs) and receptors for the Fc portion of the immunoglobulin molecules (Fc receptors) on the surface of phagocytic cells such as neutrophils and macrophages.

Diversity of Immune Responses

Different microorganisms elicit different types of immune response. Virus-infected cells elicit a cytotoxic CD8+ T-cell response; intracellular pathogens such as mycobacteria and protozoa elicit a CD4+ T-cell response, which results in macrophage activation; encapsulated bacteria elicit an opsonising antibody response; other bacteria such as *Neisseria* spp. elicit a complement-activating antibody response, which lyses the cell wall of the bacterium. The nature of the immune response is regulated by cytokines, which provide T-cell help (Th) in the course of an immune response. Thus IL-2, IL-12 and IFN-γ production induces a predominantly cellular immune response (Th1), whereas the production of IL-4 and IL-13 induces a predominantly antibody-mediated immune response (Th2).

Immunodeficiency Disorders

Immunodeficiency results from a failure or absence of elements from the immune system. They are often classified as primary or secondary. Primary immunodeficiency is divided into disorders that lead to deficiencies in

- T cells
- B cells
- Both T and B cells
- Complement
- Phagocytes
- Immunoglobulin A.[3]

Primary immunodeficiency disorders are the result of a developmental anomaly or a genetically determined defect of the immune system. Primary immunodeficiency due to an absent or non-functional gene product critical for normal function is more severe, so it tends to present early in life. Primary immunodeficiency due to aberrant regulation of lymphocyte differentiation, which is probably determined by the products of several genes and may be influenced by environmental factors, tends to be less severe so it presents later. Our understanding of the genetic basis of many of these conditions has continued to improve

Acquired or secondary immunodeficiency disorders are more common than primary immunodeficiency disorders and may present at any time after early childhood. Examples include:

- Immunosuppressive medications examples include:
  - Glucocorticoids
  - Cytotoxic agents
  - Calcineuron inhibitors
  - JAK inhibitors
  - Biological agents
  - Monoclonal antibodies
- Infections:
  - Human immunodeficiency virus (HIV)
- Extremes of age such as neonates and prematurity
- Malnutrition
- Protein-losing enteropathy
- Diabetes mellitus
- Thymectomy and splenectomy
- Major trauma and burns
- Haemopoietic stem cell transplantation

It is vital that an immunodeficiency disorder is considered in an adult patient with an unexplained abnormal propensity to infections , such as recurrent or multiple serious infections (e.g. deep abscess, meningitis, osteomyelitis, sepsis and pneumonia), persistent thrush, opportunistic infections or poor response to antimicrobial therapy and requires the demonstration of a specific immune defect (Table 85.2).

Table 85.2

Antibody Deficiency

A poor systemic antibody response most commonly results in a lack of opsonising antibody, and a propensity to infections with encapsulated bacteria such as *Streptococcus pneumoniae* or *Haemophilus influenzae* , often manifesting as recurrent respiratory tract infections including sinusitis. Chronic enterovirus infections of the nervous system and infection with some mycoplasmas may also occur in children with severe primary immunoglobulin deficiency (agammaglobulinaemia).

Primary Antibody Deficiency Disorders

Failure of B-cell production or differentiation is the cause of most primary antibody deficiency disorders. [1]

X-linked agammaglobulinaemia (XLA) is a rare disorder due to mutations of the *Btk* gene on the X-chromosome that results in the absence of a B-cell tyrosine kinase necessary for the maturation of B cells, and hence absent mature B cells in blood and secondary lymphoid tissues and consequent immunoglobulin deficiency. In the hyper-IgM immunodeficiency syndrome, B cells are able to differentiate into plasma cells secreting IgM at elevated levels, but not IgG, IgA or IgE.

Common variable immunodeficiency (CVID) is a group of disorders that appear to be the consequence of immunoregulatory defects that result in impaired B-cell differentiation, leading to hypogammaglobulinaemia. It may manifest as recurrent respiratory tract infections, enteropathy and malignancies.

IgA deficiency also results from impaired B-cell differentiation. Deficient secretory antibody responses are common in patients with IgA deficiency, but most affected individuals are able to produce compensatory secretory IgM or IgG antibody responses and are asymptomatic. Some may also have a defect of systemic antibody responses, such as an IgG subclass deficiency and/or impairment of antibody responses to polysaccharide antigens, and hence suffer from recurrent respiratory tract infections. [2]

The immunoregulatory defect underlying CVID and IgA deficiency sometimes results in an increased propensity to autoimmunity. This can include the production of anti-IgA antibodies, which may result in anaphylactoid reactions to blood products containing IgA.

Acquired Antibody Deficiency Disorders

B-cell chronic lymphocytic leukaemia or lymphoma and myeloma are commonly associated with reduced synthesis of normal immunoglobulins, which may result in bacterial infections.[3] A thymoma is a rare cause of immunoglobulin deficiency and should be considered in a patient presenting with primary immunoglobulin deficiency after the age of 40.[4]

Asplenic patients have impaired production of antibodies against polysaccharide antigens, leading to infection with encapsulated bacteria, such as pneumococcus, *H. influenzae* type B and meningococcus.[5]

Drugs occasionally affect B-cell differentiation and cause immunoglobulin deficiency, particularly IgA deficiency. The most common offender is phenytoin. Most patients do not have an antibody deficiency severe enough to cause infections. Intensive plasmapheresis may also cause severe immunoglobulin deficiency if immunoglobulin replacement is not used.

Treatment of Antibody Deficiency Disorders

Infections can be prevented by regular monthly infusions of intravenous immunoglobulin (IVIg) in patients with primary or acquired antibody deficiency. Acute infections should be treated with appropriate antibiotics. The routine use of IVIg as an adjunct in the management of sepsis in adults is not recommended, with a lack of high-quality evidence to suggest any benefit. Large, multicentre RCTs are needed to resolve the uncertainty regarding whether immunoglobulin has a role in sepsis and septic shock.[4]

Cellular Immunodeficiency

Impairment of cell-mediated immune responses leads to an increased propensity to infections normally controlled by cellular immune responses (see Table 85.2). These pathogens typically replicate intracellularly and cause persistent (latent) infections that reactivate when the cellular immune response against them becomes ineffective.

Primary Cellular Immunodeficiency

Children with DiGeorge syndrome have a complete or partial absence of the thymus, resulting in the depletion of T cells from blood and lymphoid tissue.[6]

Chronic mucocutaneous candidiasis describes a heterogeneous, and often a less severe, group of cellular immune deficiencies. In some populations, it has been associated with specific mutations in the autoimmune regulator (AIRE) gene and can be an early manifestation of the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome, together with adrenal insufficiency and autoimmune hypoparathyroidism.[7]

Acquired Cellular Immunodeficiency

HIV infection is the most common cause of acquired cellular immunodeficiency. Less common causes include Hodgkin disease, T-cell lymphomas and sarcoidosis, which may also be complicated by opportunistic infections. A thymoma is a rare cause of chronic mucocutaneous candidiasis that occurs later in life.[8]

Suppression of cellular immune responses is an intended effect of many immunosuppressant drugs used to treat allograft rejection, graft-versus-host disease (GvHD), autoimmune diseases and vasculitis. Opportunistic infections may complicate this type of immunodeficiency.

Treatment of Cellular Immunodeficiency Disorders

Most infections complicating cellular immunodeficiency are reactivated latent infections. The degree and duration of cellular immunodeficiency determine the risk and type of infection. Use of prophylactic antimicrobials is important and best defined in HIV-induced immunodeficiency.[8]

Acquired cellular immunodeficiency may be corrected by removing its cause (e.g. treating HIV or ceasing immunosuppressives). Thymus transplantation may be effective in children with thymus aplasia.

Complement Component Deficiency

Deficiency of complement components is an uncommon but often overlooked cause of recurrent bacterial infections. Complement-mediated lysis of bacterial cell walls is a critical defence against certain bacteria, especially *Neisseria* spp. and related bacteria such as *Moraxella* spp. and *Acinetobacter* spp. Deficiency of classical pathway components may also result in impaired antibody responses.

Primary Complement Deficiency

Congenital deficiency of C3 is extremely rare. C3b is an important opsonin and C3 deficiency will often impair phagocytosis of bacteria, causing a propensity to severe pyogenic infections. Deficiency of MAC components is more common, and should be considered in patients with recurrent meningococcal infections. [9] Deficiency of classical pathway components (C1, C2 and C4) may also result in an increased propensity to infection with meningococci and other bacteria, but most affected individuals do not experience recurrent infections.

Acquired Complement Deficiency

Disease processes that cause persistent activation of the complement system may cause depletion of complement components, particularly classical pathway components. This can result in infections with *Neisseria* spp. or related bacteria and sometimes overwhelming septicaemia when the complement deficiency is severe. Systemic lupus erythematosus, myeloma and chronic atrioventricular shunt infections are rare causes of complement component deficiency.

Management of Patients With Complement Deficiency

An awareness of the possibility of complement deficiency is the most important aspect of management. Replacement therapy is not available. If a complement component deficiency is identified, screening of family members should be considered.

Phagocyte Disorders

Phagocytosis of a bacterium or fungus by a neutrophil, leucocyte or macrophage is dependent on chemotaxis (attraction of phagocytes to the site of infection), adhesion (to endothelial cells via molecules such as integrins), binding (to opsonins on the microorganism), ingestion and intracellular killing (which involves both oxidative and non-oxidative mechanisms).

Depletion or functional impairment of phagocytes results in an increased propensity to bacterial and fungal infections, particularly infection with *Staphylococcus aureus* , Gram-negative enteric bacteria, *Candida* spp. and *Aspergillus* spp. Primary or acquired defects of phagocytes may result in localised pyogenic infections or pneumonia. Patients with severe neutropenia, however, may have little inflammatory reaction and overwhelming systemic infections, including systemic fungal and yeast infections, are common.

Primary Disorders of Phagocytosis

Congenital neutropenias are rare. Defects of phagocyte function usually affect chemotaxis, adhesion or intracellular killing, either alone or in combination. The best-characterised defect of phagocyte adherence results from a congenital absence of the β-subunit of CD18 integrins in patients with leucocyte adhesion deficiency syndrome type 1. [10]

Defects of intracellular killing are usually caused by a deficiency of microbicidal enzymes. Chronic granulomatous disease (CGD) results from a deficiency of a phagosome enzyme (NADPH oxidase), leading to ineffective oxidative killing. [11] CGD usually presents in childhood but may present in adults. It should be considered in patients with recurrent abscesses or suppurative lymphadenitis and in patients with pneumonia caused by *S. aureus* or *Aspergillus* spp. infection.

Acquired Disorders of Phagocytosis

Severe neutropenia may be complicated by bacterial or fungal infections. There are many causes of neutropenia, including autoimmune neutropenia, drug therapy and haematological diseases such as cyclic neutropenia, myelodysplastic syndromes and aplastic anaemia. Cytotoxic chemotherapy commonly causes neutropaenia, and is often complicated by severe bacterial and fungal infections.

Management of Phagocyte Disorders

Acquired neutropenia may be corrected by removing the underlying cause and/or use of granulocyte colony-stimulating factor (G-CSF). Febrile neutropenia requires investigation for the source of sepsis and empirical antibiotics. If fever persists, then antifungals should be added. IFN-γ therapy may be effective in patients with CGD.

Combined Immunodeficiency Disorders

Several immunodeficiency disorders result from a combination of immune defects, some of which are so severe that death is common unless the defect can be corrected. Such conditions are classified as severe combined immune deficiency (SCID) syndromes, the incidence is estimated to be approximately 1 in 60,000 births. Given advances in genetic sequence-based diagnosis it is now appropriate to refer to SCID according to the specific molecular defect of the patient, which can now be identified in most cases.

Primary Combined Immunodeficiency

There are many primary combined immunodeficiency syndromes, which present in early childhood. Specific molecular defects have now been demonstrated for many of them. For example, defective expression of MHC class II molecules, adenosine deaminase (ADA) deficiency and deficiency of the common γ-chain of the receptor for several interleukins (IL-2, 4, 7, 9, 15 and 21) all result in a deficiency and/or functional impairment of B cells, T cells and sometimes NK cells. Deficiency of the IL receptor common γ-chain results from mutations of its gene on the X-chromosome and is the underlying defect of X-linked SCID.

Treatment of primary combined immunodeficiency

HSCT is the main treatment for many types of primary SCID, though enzyme replacement therapy can be effective in ADA deficiency and gene replacement therapy has been used to treat X-linked SCID. Antibody replacement with IVIg therapy and prophylaxis for opportunistic infections are also important in primary SCID.

Acquired Combined Immunodeficiency

Combined immune defects may also be acquired from disease or its treatment.

Haemopoietic stem cell transplantation

Combined immune defects may result in severe infections in patients who have received HSCT.13 Following transplantation, an immunodeficient state exists until the recipient's immune system is reconstituted with donor cells. Consequently, both antibody-mediated and cell-mediated immunity are deficient in the first 3–4 months after transplantation and may remain deficient for a longer period of time in patients with GvHD. This immune defect is often compounded by neutropenia and/or the effects of corticosteroid or immunosuppressant therapy for GvHD. Defective antibody responses may persist for several years after transplantation, particularly antibody responses against polysaccharide antigens.

Critical illness

Patients who are critically ill, particularly as a result of surgery, trauma, burns or overwhelming sepsis, may also have acquired immune defects. The immune system responds to critical illness with a local release of inflammatory mediators and cytokines. In fact, many critically ill patients demonstrate co-existing inflammatory and counter-regulatory anti-inflammatory responses. These defects include abnormalities of cellular immunity, immunoglobulin deficiency and impaired neutrophil function and appear to be associated with an increased risk of infection. Impairment of cell-mediated immune responses usually manifests as decreased T-cell proliferation and impaired delayed-type hypersensitivity responses and probably results from a combination of factors, including the effects of anaesthetic drugs, blood transfusion, negative nitrogen balance and serum suppressor factors, including cytokines such as TNF. Phagocyte defects are mostly due to the impairment of neutrophil chemotaxis by serum factors and impaired intracellular killing. Deficiency of serum immunoglobulins also occurs, especially IgG deficiency, and may be associated with antibody deficiency. Serum leakage is a factor in patients with burns, and reduced synthesis and increased catabolism of immunoglobulins occur in many critically ill patients.

There is no specific treatment for immune defects in critically ill patients. General measures such as adequate nutrition, achieving a positive nitrogen balance and excision of burns appear helpful. Biological response modifiers, cytokine and mediator inhibitors, and IVIg therapy have all been evaluated. IVIg therapy reduces the number of acute infections, particularly pneumonia, but patient survival is not increased. [3] Administration of G-CSF is safe in intensive care patients but does not improve outcomes and is not recommended. Similar findings have been demonstrated for granulocyte-macrophage colony-stimulating factor (GM-CSF) which has also been demonstrated in a meta-analysis to improved infection resolution but has no effect on mortality, it remains not recommended as a therapy for sepsis. [10]

Asplenia and hyposplenism

The spleen is an important part of the immune system's response to infections, particularly bloodstream infections. Splenic macrophages remove opsonised microorganisms from the blood, and IgM memory B cells produce an early antibody response to the polysaccharide antigens of encapsulated bacteria. The risk of overwhelming post-splenectomy infection (OPSI) is around 1 in 500 per annum, with 50% mortality. OPSI is most commonly caused by encapsulated bacteria, such as *Pneumococcus, Meningococcus* and *H. influenzae* , for which vaccines are available. Other important infections may include group A *Streptococcus, Capnocytophaga canimorsus* (following dog bites), *Salmonella, Enterococcus* and *Bacteroides* .

Asplenic/hyposplenic patients require education, vaccination and appropriate use of antibiotics. Pneumococcal, meningococcal and *H. influenzae* vaccines, including regular boosters, and annual influenza vaccine are recommended, preferably 14 days before removal of the spleen if performed electively, or at least 14 days after if not. [12] Antibiotic prophylaxis (penicillin or if allergic, macrolides) should be given in accordance with national guidelines. Enrolment of patients in spleen registries, where available, can offer ongoing patient education, vaccination reminders and access to updated recommendations (e.g. https://spleen.org.au/VSR/index.html).

Biological immune response modulators

Anti-TNF agents such as infliximab have been associated with increased rates of bacterial infection, [13] tuberculosis and some opportunistic infections.

Antibodies targeting various B- and T-cell antigens are increasingly used for rheumatological and haematological diseases. Not unexpectedly, these agents are associated with infections. For example, the anti-CD20 antibody rituximab specifically targets B cells for its therapeutic action but is associated with infectious complications such as recurrent bacterial infection, reactivation of hepatitis B, cytomegalovirus (CMV) infection and progressive multifocal leukoencephalopathy (PML).

Implications of solid tumours for intensive care

Timothy Wigmore, Pascale Gruber and Sef Carter

Solid tumours and their implications in the ICU

The term solid tumour refers to masses of tissue not containing cysts or liquid. There are over 200 types and they are classified according to the tissue of origin. The majority arise from epithelial tissues and are termed carcinomas. They are further differentiated into squamous cell (which include tumours of skin, oropharynx, oesophagus, cervix and lung) and adenocarcinomas (which include those originating in lung, colon, breast, pancreas and stomach). Rarer tumours originate from connective tissue (sarcomas), the neuroectoderm (gliomas, glioblastomas, neuroblastomas and medulloblastomas) or germ cells (teratomas, seminomas and choriocarcinomas).

There were 19.4 million new cancer cases worldwide in 2020 and this number is expected to reach 28.4 million by 2040.[1] This increase is attributable to an ageing population and lifestyle changes, with diet, lack of physical activity and obesity all playing a role. The most frequently diagnosed cancers worldwide are breast (11.7% of the total), lung (11.4%) and prostate cancer (7.3%), while the commonest causes of death due to cancer are lung (18% of the total), liver (8.3%) and stomach cancer (7.7%).[1]

This caseload presents a substantial challenge to intensive care physicians. In the Sepsis Occurrence in Acutely Ill Patients (SOAP) study cancer patients accounted for 15% of all ICU admissions, 85% of which were solid tumours. [2] The Intensive Care National Audit and Research Centre case mix review of 128 adult general ICUs in the United Kingdom demonstrated that bowel and oesophageal tumours accounted for the fourth and eighth most common reason for ICU admission respectively. [3]

Cancer treatments fall broadly into four main categories: chemotherapy, immunotherapy, radiotherapy and surgery. The term ‘systemic anti-cancer therapy’ (SACT) is increasingly used when discussing chemotherapy or immunotherapy. Many patients have a combination of all four, and it is increasingly common for patients to receive neoadjuvant chemotherapy to facilitate surgical resection. Chemotherapeutic agents affect DNA synthesis, structure or repair and are usually unselective in that they affect all rapidly dividing cells. They may therefore also affect cells in the gut (with resulting mucositis and diarrhoea), bone marrow (leading to thrombocytopenia, anaemia and neutropaenia) and hair follicles (causing alopecia). Additionally, many chemotherapeutic drugs have agent-specific side effects which may have implications for ICU (see Table 86.1). Chemotherapy-induced toxicities and typical side effects include pyrexia, rigours and malaise, with the risk of neutropaenia greatest within the first two weeks of administration. Care of the neutropenic patient in the intensive care setting is detailed in the chapter on haematological malignancies. Certain chemotherapeutics are associated with specific toxicities, which may arise during the post-operative period, or necessitate admission to intensive care.

Table 86.1

GI , Gastrointestinal.

Bleomycin-related lung injury

Bleomycin is a glycopeptide derived from the Streptomyces spp. used for the treatment of head and neck squamous cell carcinomas, cancers of the cervix, germ cell tumours and Hodgkin's lymphoma. Bleomycin-induced pneumonitis (BIP) is estimated to occur in up to 40% of patients, with mortality rates approaching 25%. [4] Toxicity is caused by the generation of oxygen-free radicals with subsequent alveolitis and fibrosis. Patients older than 40 years old are at higher risk of toxicity. [5] This is exacerbated by supplemental oxygen therapy and BIP may have a delayed onset up to 6 months following treatment. Subacute progressive pulmonary fibrosis may occur several years after treatment.

Ifosfamide neurotoxicity

Ifosfamide is an alkylating agent used in the treatment of cancer of the ovary, breast, lung, testicles, and lymphoma. Ifosfamide-induced encephalopathy develops in 10% to 30% of patients, with a severity ranging from mild confusion and hallucinations to extra-pyramidal symptoms, seizures and coma. Symptoms typically occur within 2 to 96 hours of infusion and improve within 72 hours of cessation of ifosfamide. The diagnosis is essentially one of exclusion with normal brain imaging and an EEG demonstrating metabolic encephalopathy. The aetiology is thought to be related to direct toxicity from metabolites of ifosfamide, notably chloracetaldehyde and dicarboxylic acid. [6] The incidence is greater in those with pre-existing low albumin, raised creatinine or with cisplatin pretreatment. [7] Methylene blue (50 mg 4 hours intravenously) has been shown to ameliorate or even terminate symptoms. [8]

Anthracycline cardiomyopathy

Anthracyclines cause dose-related cardiotoxicity. [9] Acute toxicity manifests as atrial or ventricular arrythmias typically within the first two weeks of treatment and is usually benign. Non-specific ECG changes such as QTc prolongation, ST-segment changes and T-wave flattening are frequently observed. [10] Early onset chronic toxicity, occurring within the first year following treatment, accounts for 98% of cases and presents as progressive left ventricular dysfunction and cardiac failure without reversibility.

Resultant heart failure should be managed with prognosis-modifying medications and consideration for cardiac resynchronisation. [11]

5-Fluorouracil (5-FU) cardiotoxicity

5-FU and the oral prodrug capecitabine are frequently used in the treatment of breast and gastrointestinal cancer. Cardiotoxicity manifests as angina due to coronary artery vasospasm with serious complications such as myocardial infarction, cardiogenic shock and cardiac arrest occurring in up to 2% of cases of toxicity. [12]

Immunotherapy

Immunotherapy is increasingly used in the treatment of solid tumours with the established use of monoclonal antibodies such as trastuzumab and cetuximab for breast and bowel cancer respectively. Immune checkpoint inhibitors (ICIs) are an expanding class of monoclonal antibodies which antagonise the upregulated immunotolerance that co-inhibitory signalling pathways such as cytotoxic T-lymphocyte–associated molecule-4 (CTLA-4), programmed cell death receptor-1 (PD-1), and programmed cell death ligand-1 (PD-L1) confer to malignant cells. ICI disruption of the ligand–receptor binding between malignant cells and T-cells enables T-cells to correctly identify and attack malignant cells. ICIs are used in a wide range of cancers such as: metastatic melanoma, renal cell carcinoma and non-small cell lung cancer (see Table 86.2).

Table 86.2

Table of immunotherapies and clinical indication

DRUG NAME OR GROUP	SOLID TUMOURS FOR WHICH ARE TYPICALLY USED	TARGET
Ipilimumab	Melanoma, RCC	CTLA-4
Tremelimumab	NSCLC	CTLA-4
Nivolumab	Melanoma, RCC, NSCLC, HNSCC, UC, HCC, SCLC	PD-1
Pembrolizumab	Melanoma, NSCLC, HNSCC, UC	PD-1
Atezolizumab	NSCLC, UC	PD-L1
Avelumab	Merkel cell carcinoma, UC	PD-L1
Durvalumab	NSCLC, UC	PD-L1
Trastuzumab	Breast cancer	HER2
Olaratumab	Sarcoma	PDGFR alpha
Ramucirumab	Gastric cancer	VEGFR2
Cetuximab	HNSCC, bowel cancer	EGF-R

CTLA-4 , Cytotoxic T-lymphocyte associated protein 4; *EGF-R* , epidermal growth factor receptor; *HER2* , human epidermal growth receptor 2; *HNSCC* , head and neck squamous cell carcinoma; *NSCLC* , non-small cell lung carcinoma; *PD-1* , programmed cell death protein 1; *PDGFR α* , platelet-derived growth factor receptor α; *PD-L1* , programmed death ligand 1; *RCC* , renal cell carcinoma; *SCLC* , small cell lung cancer; *UC* , urothelial carcinoma; *VEGFR2* , vascular endothelial growth factor receptor 2.

Immune checkpoint inhibitors

ICI-related end-organ dysfunction shows variable degrees of reversibility and may result in dermatitis, colitis, pneumonitis, hepatitis, nephritis, myocarditis, uveitis, endocrinopathies, encephalopathy and haematological toxicity. The mechanism for immune-related adverse events (irAEs) likely occurs through a combination of anti-tumour mediated immune activation, and off-target effects. IrAEs have been reported to occur in over 70% of patients receiving Ipilimumab with up to 25% of patients experiencing severe toxicity which may warrant ICU admission.[13] IrAEs typically occur within the first six months of treatment, with the majority in the first month.

Fatal toxicities occur in less than 2% of patients and are typically due to severe colitis, pneumonitis, hepatitis, neurological or haematological dysfunction. Pneumonitis is most frequently observed in patients with non-small cell lung carcinoma and may mimic pneumonia, progression of metastatic disease or diffuse alveolar haemorrhage. Myocarditis is rare, and occurs in less than 1% of patients, but is associated with a mortality rate approaching 40%.[14] Neurological irAEs may affect the central nervous system (meningoencephalitis), peripheral nervous system (polyneuropathy, Guillain-Barré syndrome) or the neuromuscular junction (myasthenia gravis or Lambert-Eaton myasthenic syndrome). There is no single diagnostic test to confirm irAEs and testing should be directed towards ruling out other aetiologies of organ dysfunction. In cases of irAEs affecting the kidney, liver, colon or skin a biopsy should be considered to confirm the diagnosis. Low-grade chronic toxicities are increasingly recognised and typically manifest as endocrinopathies such as hypothyroidism and hypoadrenalism.[15]

Early identification of toxicity and withdrawal of the offending ICI with or without immunosuppression with corticosteroids is often sufficient to control low-grade (grade ≤ 2) toxicity.[16], [17] Early use of high-dose corticosteroids may, however, be associated with lower rates of progression-free survival and overall survival.[18], [19] Refractory cases may require treatment with anti-TNF alpha agents, calcineurin inhibitors, mycophenolate mofetil or specific biological agents, such as Vedolizumab for colitis.[20]

Monoclonal antibodies

Infusion of monoclonal antibodies typically provokes a self-limiting ‘flu’-like syndrome, however, fatal infusion reactions are uncommon. Trastuzumab causes a non-dose related, reversible myocardial dysfunction with the majority of patients recovering following discontinuation of the drug. Cohort studies report the incidence of left ventricular impairment to be between 10% and 45%. [21] Its occurrence does not preclude future dosing providing cardiac function has recovered prior to further use. [22]

Radiotherapy

Radiotherapy causes damage to cells through the production of oxygen-free radicals by the ionisation of water molecules. These in turn cause damage to cellular DNA. Damage to healthy surrounding tissue is minimised by targeting the radiation beam through multiple planes that intersect within the tumour. Despite this, radiation commonly causes acute inflammation and subsequent fibrosis in the tissues through which it passes. Common examples are pericarditis, pericardial, myocardial, skin and lung fibrosis. This can cause organ dysfunction, particularly when combined with a chemotherapeutic agent known to have toxicities associated with that same organ.

Oncological emergencies

Spinal cord compression

Breast, prostate, lung, and kidney cancers have a predilection for bony metastasis. High spinal cord compression may require semi-urgent invasive mechanical ventilation. Treatment usually takes the form of moderate-dose steroids followed either by surgery or radiotherapy. [23]

Cardiac Tamponade

Pericardial effusions due to epicardial metastasis or mediastinal lymph drainage obstruction are relatively common with advanced lung and breast cancers. [24] Rapid accumulation of 200–300 mL of pericardial fluid may result in cardiac tamponade while chronic effusions may be as large as 1–2 litres before diastolic filling is impaired. Echocardiography classically demonstrates right atrial collapse during late diastole and right ventricular collapse during early diastole. Inferior vena cava dilation (>20 mm) without inspiratory collapse is a sensitive but non-specific sign. The management of cardiac tamponade in the acute setting is pericardiocentesis with subsequent pericardial window formation. For some tumours, treatment of underlying cancer with chemotherapy and/or radiotherapy will result in longer-term resolution.

Electrolyte disorders

Rapid and life-threatening changes in electrolyte concentrations may result from paraneoplastic disorders, losses from treatment-induced diarrhoea or renal dysfunction. Paraneoplastic disorders result from the secretion of hormones or hormone-like substances from tumours. Syndrome of inappropriate anti-diuretic hormone secretion (SIADH) typically occurs in the setting of small cell lung carcinomas which account for 80% of the total incidences of SIADH. SIADH also occurs with pancreatic, colonic, prostate, duodenal and head and neck tumours. It can be seen with cisplatin, ifosfamide, vincristine, vinblastine and cyclophosphamide use. Hyponatraemia is particularly marked when secondary to cyclophosphamide due to concurrent fluid loading to reduce the risk of haemorrhagic cystitis. [25] Chronic mild hyponatraemia (Na+ >125 mmol/L) rarely requires intervention while severe hyponatraemia (Na+ <125 mmol/L) should be cautiously corrected to avoid osmotic demyelination.

Hypercalcaemia represents the most common metabolic consequence of solid tumours and occurs in 10%–20% of patients. [26] The release of parathyroid hormone-related peptides from lung, head and neck, kidney and pancreatic cancers, together with osteolytic calcium release from tumours with bony metastases (e.g. breast and prostate) can result in life-threatening hypercalcaemia. Treatment of hyperkalaemia is with a combination of saline rehydration, calcitonin, and antiresorptive agents such as bisphosphonates (e.g. pamidronate) or receptor activator of nuclear factor kappa-B ligand (RANKL) inhibitors (e.g. denosumab). Saline corrects hypercalcaemic-induced dehydration, calcitonin reduces resorption from bone by blocking osteoclast maturation and increasing renal calcium excretion and bisphosphonates cause osteoclasts to apoptose. [27] Glucocorticoids are used in cases of excess 1,25 dihydroxyvitamin D, or excess endogenous calcitriol (such as in cases of lymphoma). The response to furosemide is variable and often requires the use of high doses resulting in electrolyte abnormalities and is therefore not recommended. [28] The effect of bisphosphonates may be poor in those with parathyroid hormone-related protein (PTHrP) induced hypercalcaemia, although zolendronic acid may be useful. [29], [30]

Hypokalaemia requiring admission to the ICU is often the result of diarrhoea due to chemotherapy or radiotherapy. Hypokalaemia may also be caused by ACTH-producing lung tumours, notably bronchial carcinoid tumours, or from tumours that produce insulin.

Electrolyte disorders may be of sufficient severity to be life-threatening requiring immediate correction with intravenous replacement. They are also often accompanied by a normal anion gap hyperchloraemic metabolic acidosis caused by concomitant bicarbonate loss. This can result in marked acidaemia with consequent respiratory compensation that can lead to exhaustion in an already debilitated patient. It is best managed with bicarbonate replacement, although care needs to be taken to avoid worsening hypokalaemia. Electrolyte abnormalities and acute kidney injury can also be seen in the context of tumour lysis syndrome (TLS). TLS may be seen in small cell lung tumours, neuroblastomas and carcinoma of the breast but is more commonly seen in haematological cancers. Further information on TLS can be found in the chapter on Haematological malignancy.

Superior mediastinal syndrome

Patients with anterior mediastinal compression typically present to the ICU either post-operatively or as an emergency with airway obstruction, cardiac compression or superior vena cava obstruction. The aetiology in adults is most commonly a thymoma, although lymphomas, germ cell tumours and sarcomas can also be responsible.[31] Airway obstruction may occur due to compression of the trachea or bronchi. In an emergency, there is often little time for formal assessment. Imaging may be available in the form of CT or MRI demonstrating the level and degree of compression. A decrease in cross-sectional area of 50% is predictive of airway complications.[32,33] If available, and symptoms permit, a CT scan can be conducted with the patient at 20–30 degrees of head up or in lateral or prone position to minimise airway compromise. Flow volume loops can demonstrate intrathoracic or extrathoracic airway obstruction although correlation with subsequent airway obstruction is variable.

Induction of anaesthesia may result in catastrophic airway obstruction due to a reduction in intrathoracic volume, increased size of (often very vascular) tumours with increased central blood volume and increased compressibility of airways with reduction in smooth muscle tone. Equally cardiovascular collapse may occur due to compression of the pulmonary arteries or superior vena cava. Should it be necessary to intubate the patient with superior mediastinal syndrome there are a number of key points that need to be considered.[34,35]

1. Establish venous access in the lower half of the body in case of superior vena caval obstruction which would result in significantly slowed transit of administered drugs and fluids. Maintain continuous intravenous fluid administration to minimise the cardiovascular effects of vascular obstruction during induction.
2. An awake fibreoptic intubation with local topicalisation should be strongly considered to prevent the risks associated with the induction of anaesthesia and maintain spontaneous respiration. In high-risk cases, establishment of femoral veno-venous bypass under local anaesthesia prior to induction offers a route out in the event of complete airway obstruction. Having a bypass on “standby” is unlikely to be adequate due to the time required to establish it in the event of an emergency.

3. Neuromuscular blockade is best avoided. Subsequent positive pressure ventilation (in concert with smooth muscle relaxation) may cause worsened bronchiolar obstruction leading to atelectasis and ventilation/perfusion mismatch. It will also increase the pressure of the mass on mediastinal structures such as the Superior Vena cava, heart and pulmonary arteries with consequent potential cardiovascular collapse. If blockade is necessary, a short-acting agent should be considered in the first instance.
4. Should airway obstruction or cardiovascular collapse occur following intubation, repositioning the patient either sitting up, laterally or prone may be effective by reducing the mass effect. If this is ineffective and veno-venous bypass is not possible, then emergency thoracotomy with manual displacement of the mass can be considered.

Superior vena cava compression

Superior vena cava (SVC) compression may be part of the superior mediastinal syndrome but often occurs in isolation. When caused by a tumour, the aetiology is normally lung cancer, lymphoma or a germ cell tumour. [36] The clinical presentation depends on the time period during which the compression has evolved as collaterals involving the azygos, internal mammary or oesophageal vessels develop over time and relieve the pressure. Patients typically present with facial and arm swelling, dyspnoea, cough and dysphagia. Those presenting to the ICU are likely to have more immediately life-threatening features either of airway obstruction or cerebral oedema in which case they may have stridor and a headache or a decreased level of consciousness. [37] Endovascular stenting results in rapid resolution of symptoms in the vast majority of cases and can be undertaken even in cases of complete obstruction. [38] Radiotherapy is also effective in reducing tumour burden and achieving disease control in those cancers that are radiosensitive (which includes the majority responsible for SVC obstruction), but takes up to 4 weeks to take effect and can make subsequent histological diagnosis impossible. Steroids such as dexamethasone have a role in cases where the tumour is known to be steroid sensitive (for example with lymphomas or thymomas) but are otherwise not indicated. [39]

Malignant pleural effusions

Pleural effusions arising due to the infiltration of malignant cells in the pleural space most commonly arise in patients with lung cancer, mesothelioma, metastatic gastrointestinal and genitourinary cancer and lymphoma. Massive pleural effusions resulting in complete or near complete opacification of the hemithorax are usually malignant. Diagnostic pleural aspirations may be considered for smaller effusions, and pleural fluid samples should be sent for cytological analysis – in addition to routine tests – to confirm the presence of malignant cells. The indications for pleural drainage are the same as for cases of non-malignant aetiology, such as dyspnoea and hypoxia. A maximum of 1 to 1.5 litres of fluid should be drained every 2 to 4 hours to prevent complications such as re-expansion pulmonary oedema or cardiovascular instability. Cases of recurrent symptomatic pleural effusions may be considered for pleurodesis or placement of indwelling pleural catheters.

Use of chemotherapy in the ICU setting

There is little published data on the administration of chemotherapy for solid tumours in the ICU. Chemotherapy in the ICU should be considered if its administration results in amelioration of life-threatening symptoms or a significant chance of improved patient outcome. [40], [41] Prognostic indicators following chemotherapy administration appear to be similar to those for the general critically ill patient with cancer. [42]

The effect of critical care on cancer

There has been little work looking into the effect of an ICU stay on tumour progression but much of what happens to a patient during this period (be it disease or treatment-mediated) has an impact on the function of the immune system and a potential consequent effect on tumour growth and metastases.

Studies conducted in animals have shown that surgery in itself promotes metastasis. This is likely due to a combination of the production of pro-inflammatory stimulators of tumour growth, the release of tumour cells directly into the circulation and the stress response. Circulating catecholamines activating the beta-2-receptors directly remodel the tumour microenvironment with increased production of pro-metastatic cytokines such as vascular endothelial growth factor, promoting angiogenesis. Furthermore, catecholamines reduce the activity of cytotoxic T and natural killer (NK) cells to respond to tumour cells. [43]

The use of sedatives, induction agents and analgesics may also impact on cancer progression. Neuraxial anaesthesia has been shown to reduce circulating catecholamines, inflammation and immunosuppression. [44] Opioids which are commonly used for cancer-related pain have been shown to have variable in vivo and in vitro effects on NK and T cell activity. [45] However, studies evaluating the clinical significance of such findings in terms of recurrence of malignant disease or survival report mixed results. [46] Hypoxia-inducible factors 1-alpha and 2-alpha are induced by hypoxia and have also been implicated in the survival and metastasis of malignant cells. [47] In summary, admission to ICU for a patient with cancer carries a significant potential risk of promoting tumour growth and metastasis and further work is needed to evaluate potential targets to reduce the risk of immune escape and circulating tumour cell deposition.

Outcomes for patients admitted to ICU with solid tumours

The traditional view of the outcome for the critically ill cancer patient has been one which is universally poor, but it is now accepted that the outcome for these patients is similar to that for other acutely ill patients with underlying chronic disease. Improvements in general ICU care, reduced cytotoxicity of chemotherapeutic regimes and the development of novel anti-bacterial and anti-fungal agents have demonstrated improved survival rates over time for patients admitted to the ICU with solid organ tumours. However, accurate prognostication in patients with cancer and ≥1 organ failure can be difficult and highlights the complex interaction between the burden of oncological disease, complications of oncological disease and treatment(s) and co-morbid conditions when determining whether a patient should be admitted to the ICU. [48]

Studies have demonstrated some specific associations between outcomes and presenting pathologies. Oncology patients admitted with sepsis and acute respiratory failure have a higher mortality than patients admitted without an underlying malignancy [49-51] and predictors of short-term mortality in solid cancer patients admitted to the ICU include greater severity illness scores, mechanical ventilation, vasopressor use, renal replacement therapy and poor performance status. [52], [53] Neutropaenia is not associated with increased mortality and even the extent of oncological disease with or without metastasis has been inconsistently associated with mortality. However, the progression of organ dysfunction over 72 hours following ICU admission has also been shown to be indicative of poor outcomes and should prompt discussion with the oncologist and palliative care regarding the appropriateness of ongoing high-intensity organ support. [54]

Return to intended oncological therapy (RIOT)

Given that the intention in most cases of admission of critically ill cancer patients to ICU is to enable return to intended oncological therapy there is a surprising dearth of data. Studies of patients with advanced lung cancer admitted to the ICU report that of 777 patients, only 150 returned to further cancer treatment. [55-59] It may be appropriate in selected cases to administer SACT in the ICU, however, this is dependent on access to oncological support, nurses trained in administering SACT and careful patient selection. [60], [61]

Quality of life and long-term outcomes

There are also few studies reporting either the quality-of-life measures or long-term outcomes (1 year or more). In the two largest studies, quality of life (as measured by SF-36 and EurQoL-5D) was poor in survivors at 3 months but recovered somewhat at a year, while the probability of quality-adjusted survival in medical patients at 18 months was just 19%.[62,63]

Māori, Aboriginal and Torres Strait Islander populations and critical illness: an overview

Paul Secombe, Alex Brown and Alex Browne

Introduction

First Nations peoples, those ethnic groups who are the earliest known inhabitants of an area having had a historical continuity with pre-invasion and pre-colonial societies that developed on their territories, experience higher rates of ill health and have shorter life expectancy than other groups living in the same country. [1] Inequity in health and health outcomes burdens First Nations populations with more disability and death at a substantially younger age. Structural barriers which hinder access to appropriate health care include geographical isolation, socioeconomic status and systemic racism. [1] First Nations people across the world face inequality in healthcare delivery, and health outcomes, and can be identified in vastly disparate First Nations groups from North America, Asia, Africa, the Arctic, Central and South America, the Pacific and the Russian Federation. [1] While acknowledging these differences are global, for the purposes of this chapter we focus on the Māori and Aboriginal and Torres Strait Islander peoples, the First Nations people of *Aotearoa* New Zealand (NZ) and Australia respectively.

First Nations peoples have a shared experience of colonisation which has been defined as – ‘the action or process of establishing a colony or colonies in a place, especially as part of an effort … to appropriate the area settled and to assert political control over any indigenous inhabitants.’[2] Colonisation has had, and continues to have, a profound impact on the lives of First Nations peoples. Direct effects include the introduction of contagious diseases for which Indigenous peoples had no or little resistance and legislative acts which sought to suppress traditional practice, such as the Tōhunga Suppression Act of 1907 which made Māori traditional medicine illegal in *Aotearoa* NZ, and legislation which supported the policy of removing children from Aboriginal and Torres Strait Islander families within Australia.[3,4] Indirect effects include land confiscations (see in particular the maps depicting decreasing Māori land holdings over time), suppression of culture and language and the introduction of alcohol and tobacco.[5,6]

Intensivists lead a multi-disciplinary team that specialises in delivering holistic care to the critically ill patient, and their family, that is personalised to each patient’s unique setting. An appreciation of how and why critically ill Māori and Aboriginal and Torres Strait Islander patients differ from other patients is required for all clinicians who aspire to work in critical care.[7,8]

Māori and Aboriginal and Torres Strait Islander Populations

Māori comprise 17% of the population in Aotearoa NZ, and Aboriginal and Torres Strait Islander comprise approximately 3.8% of the Australian population.[9,10] Both groups have hospitalisation rates higher than expected. In both countries, there are marked economic, health and educational differences when compared to non-indigenous populations.[11-13] These differences are compounded by several moderators of health outcome including geographical access to health care services, the availability of culturally appropriate services and socio-economic disadvantage. First Nations populations are less likely to live in major urban population centres where most health services are located. In particular, this applies to so-called ‘high end’ ICU services such as extra-corporeal membrane oxygenation.[7,8,14,15] Furthermore, the availability of culturally appropriate health care service has been shown to influence the likelihood of use. Both Māori and Aboriginal and Torres Strait Islander peoples report substantial difficulties accessing health services when they need to, citing both racism and negative experiences related to cultural insensitivity as the main reasons.[16-19] This is compounded by differences in socio-economic advantage. Both Māori and Aboriginal and Torres Strait Islander are more likely to live in inadequate housing characterised by over-crowding, and are more likely to reside in areas associated with increased disadvantage.[7,8,20]

Together these can be summarised under a heading of *social determinants of health* . Indeed, the Australian Institute of Health and Welfare estimates that one-third of the health gap for the Aboriginal and Torres Strait Islander population can be attributed to these factors.[21]

Despite being separated by the Tasman Sea there are important similarities in the chronic disease burden borne by Māori and Aboriginal and Torres Strait Islanders. Both suffer higher rates of diabetes (particularly type II), obesity, cardiovascular disease and chronic kidney disease and the onset of these is at a younger age. They contribute to a disproportionate rate of preventable hospital admissions.[22,23] Despite higher chronic co-morbidities, access to and provision of specialist care and drugs is lower for both Aboriginal and Torres Strait Islander and Māori patients.[23,24]

Notwithstanding the profound effects of colonisation, Māori and Aboriginal and Torres Strait Islander concepts of land and of 'country' remain strong and distinct from European ones. Similarly, health and disease are viewed differently. Mason Durie describes 'Te Whare Tapa Whā' (house of four sides), a Māori representation of health and wellbeing embodied as a sacred house which emphasises a balance which must be maintained amongst four essential components. It is best visualised rather than described (Fig. 87.1).[25] Likewise, a qualitative study examining attitudes to organ donation amongst Central Australian Aboriginal hospital staff highlighted the central role of country, families, family relationships and their roles in maintaining health. 50 This study also highlighted that Western models of assigning senior next of kin may not be appropriate, and cultural brokerage in this area is important in identifying who is the most appropriate family member to accept responsibility for consenting to procedures when the patient is unable to. Similarly, in Aotearoa New

Zealand the role of whanau (family) differs from the Western nuclear family model. Whanau conferences may include many individuals and identifying a spokesperson for the wider whanau is a vital early step in maintaining good communication. There is evidence from other spheres of medicine, including renal and cardiology, that the inclusion of an Aboriginal Health Practitioner in the clinical team has positive effects on interactions between clinicians and patients, with improved outcomes – some of which are due to improved culturally safe communication. [26-28]

The house-shaped diagram represents the Maori Hauora model of well-being. The central label reads Hauora well-being. The house has four main supporting walls or sides, each labelled with a different dimension of well-being. On the left is Taha Tinana for physical well-being. Along the left roof slope is Taha Wairua for spiritual well-being. Along the right roof slope is Taha Hinengaro for mental and emotional well-being. On the right side is Taha Whanau for family and social well-being. The base of the house is labelled Whenua (Land, roots), representing the foundation and source of strength. Each element contributes to overall well-being, symbolically structured like the parts of a traditional Maori meeting house.

FIG. 87.1 ‘Te Whare Tapa Whā’ representing the four cornerstones of Māori well being (Hauora); physical health (Taha tinana), spiritual health (Taha Wairua) family health (Taha whānau) and mental health

(Taha hinengaro) connected to land (Whenua) which forms the foundation.

What Australia lacks, and Aotearoa NZ has implemented is a treaty between colonisers and First Nations peoples. The Treaty of Waitangi, signed on the 6th February 1840, but largely ignored for the subsequent 120 years, now forms the basis of all policy decision making including health in New Zealand. [29] One of the basic tenets of the treaty is that Māori should have equitable access to health care and expect the same outcomes as non-Māori. [29] Many have argued that the absence of such a treaty in Australia contributes to the failure of policy to close the gap in all healthcare measures.

With this background to the important differences between First Nations and non-First Nations peoples of Aotearoa NZ and Australia, an exploration of First Nations patients in the ICU can be undertaken.

Clinical Presentation

Demographics

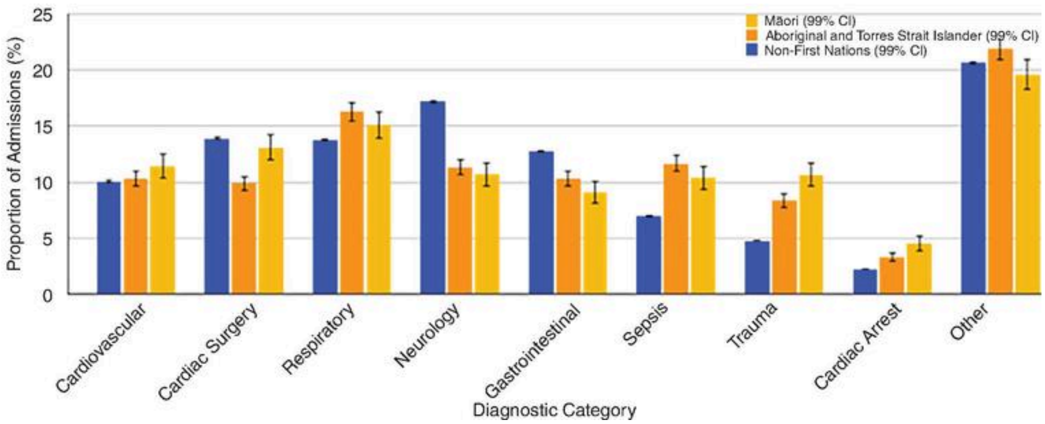
Both Māori and Aboriginal and Torres Strait Islander people are over-represented within preventable hospital admissions, including admissions to ICU. [7, 8, 13, 30-32] Moreover, Māori critically ill patients are a median of 13 years younger than those of non-Māori ethnicity and Aboriginal and Torres Strait Islander patients are a median 15 years younger than non-Aboriginal and Torres Strait Islander critically ill patients. This is perhaps in part reflective of the different underlying age distributions in each population. It is, however, worth observing that the 6th decade of life is often a time of peak career and family productivity. Both Māori and Aboriginal and Torres Strait Islanders are more likely to be admitted to a rural/regional ICU and are more likely to have residential addresses within areas of elevated socioeconomic disadvantage. Indeed more than 25% of critically ill Aboriginal and Torres Strait Islander patients have a residential address in the lowest socio-economic decile. [8, 33]

Similarly, and reflective of the higher burden of chronic co-morbid disease borne by First Nations populations globally, both Māori and Aboriginal and Torres Strait Islander critically ill patients have significantly more diabetes and significantly more dialysis-dependent kidney disease (CKD5D).[7,8] While the outcome of CKD5D patients with critically illness internationally is often poor, the outlook for Aboriginal and Torres Strait Islander and Māori patients with CKD5D admitted to ICU in Aotearoa NZ and Australia appears to be less pessimistic.[34-36] The reasons for this are not clear and may reflect the younger age of CKD5D patients in the Māori and Aboriginal and Torres Strait Islander populations.

Illness severity (as measured by APACHE II or III) is similar for critically ill Māori/Aboriginal and Torres Strait Islanders compared to non-Māori/non-Aboriginal and Torres Strait Islander. However, APACHE scores include an age sub-component. Once this is allowed for, it becomes apparent that Māori and Aboriginal and Torres Strait Islander patients admitted to ICU have a much higher degree of physiological derangement.[7,8]

Why Are Patients Admitted?

An analysis of diagnostic codes shows that both Māori and Aboriginal and Torres Strait Islander critically ill patients are more likely to be admitted for sepsis, major trauma and following cardiac arrest (Fig. 87.2).[7,8,37] It is likely disparities in social determinants of health (such as over-crowded housing) are substantial contributors to the comparatively high rates of sepsis seen in Māori and Aboriginal and Torres Strait Islander critically ill patients.[7,8,38-40]



A bar graph shows the proportion of I C U admissions across nine diagnostic categories by three population groups, such as Maori, Aboriginal and Torres Strait Islander, and Non-First Nations. The vertical axis shows the proportion of admissions in percentage from 0 to 25. Diagnostic categories along the horizontal axis include cardiovascular, cardiac surgery, respiratory, neurology, gastrointestinal, sepsis, trauma, cardiac arrest, and other. Each group is represented by a colour-coded bar with 99 percent confidence intervals. Non-First Nations admissions are highest in neurology and other categories. Māori and Aboriginal and Torres Strait Islander groups show slightly higher proportions in sepsis, trauma, and cardiac arrest compared to non-First Nations. The chart illustrates variation in I C U diagnostic category distribution by ethnicity.

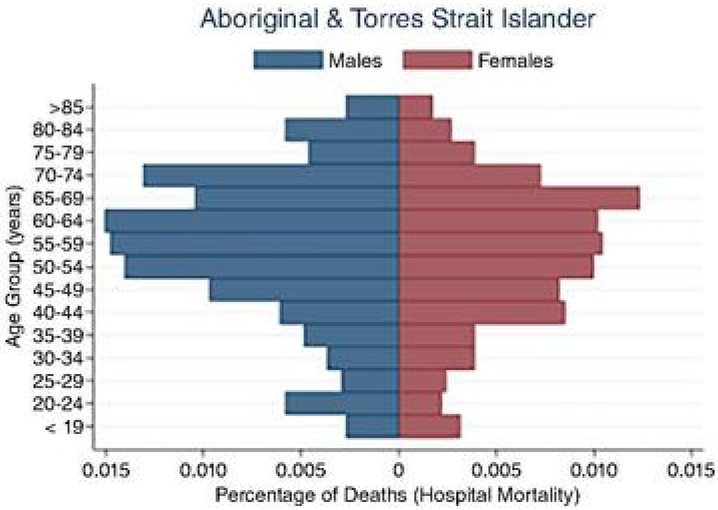
FIG. 87.2 Admission diagnostic category by First Nations status. (From Australian and New Zealand Intensive Care Society Centre for Outcome and Resource Evaluation (ANZICS CORE).)

Conversely, Aboriginal and Torres Strait Islander people, in particular, are under-represented in admissions following cardiac surgery (despite the higher burden of cardiovascular disease and rheumatic valvular disease amongst the Aboriginal and Torres Strait Islander population) and gastrointestinal diagnoses, which are likely to represent an absence of access to specialist care.[7] Further, the near complete absence of Aboriginal and Torres Strait Islander patients in private ICUs in Australia highlights the disparity between Aboriginal and Torres Strait Islander and non-Aboriginal and Torres Strait Islander populations.[7]

The higher proportion of emergency ICU admissions seen amongst Māori and Aboriginal and Torres Strait Islander critically ill populations, together with the heightened deranged physiology may be a product of both endemic health disparities and cultural and social determinants that impede First Nation people's access to health care. More equitable access to culturally appropriate services is likely to result in better management of chronic disease, mitigate the effects of acute illness and reduce the likelihood of deterioration to the point where an ICU admission is required.[7,8,33,41] This is an area where intensivists can be advocates for First Nations populations.

Outcomes

Unadjusted hospital mortality outcomes are similar for Māori and Aboriginal and Torres Strait Islander critically ill patients when compared to non-Māori/non-Aboriginal and Torres Strait Islander patients. However, unadjusted mortality outcomes obscure the fact that Māori and Aboriginal and Torres Strait Islander critically ill patients are 13–15 years younger than their non-First Nations critically ill peers. This is further highlighted by the age distribution of deaths for critically ill patients (Fig. 87.3). After adjustment for age and illness severity (among other confounders), the long-term mortality outcomes for critically ill Māori and Aboriginal and Torres Strait Islander patients are worse, while Aboriginal and Torres Strait Islander patients are also more likely to be readmitted to ICU in a subsequent hospital admission.[8,33,42] Cultural and socio-economic disadvantage appear to be carried through to the ICU and are, perhaps, the principal determinants of long term outcomes.[41,43,44]



Three bar charts compare hospital mortality by age group and sex. Each chart has age groups on the vertical axis, ranging from under 19 to over 85 years. The horizontal axis shows the percentage of deaths due to hospital mortality. The top left chart is labelled Aboriginal and Torres Strait Islander and shows broader bars for midlife age groups, especially 55 to 69. The top right chart is labelled Maori and also shows increased mortality in midlife age groups, especially 55 to 64, with higher values than the first chart. The bottom centre chart is labelled Non-Indigenous (Australia and Aotearoa New Zealand) and shows a mortality distribution that increases progressively with age, peaking at the oldest age groups, and displaying a more symmetrical pattern between males and females.

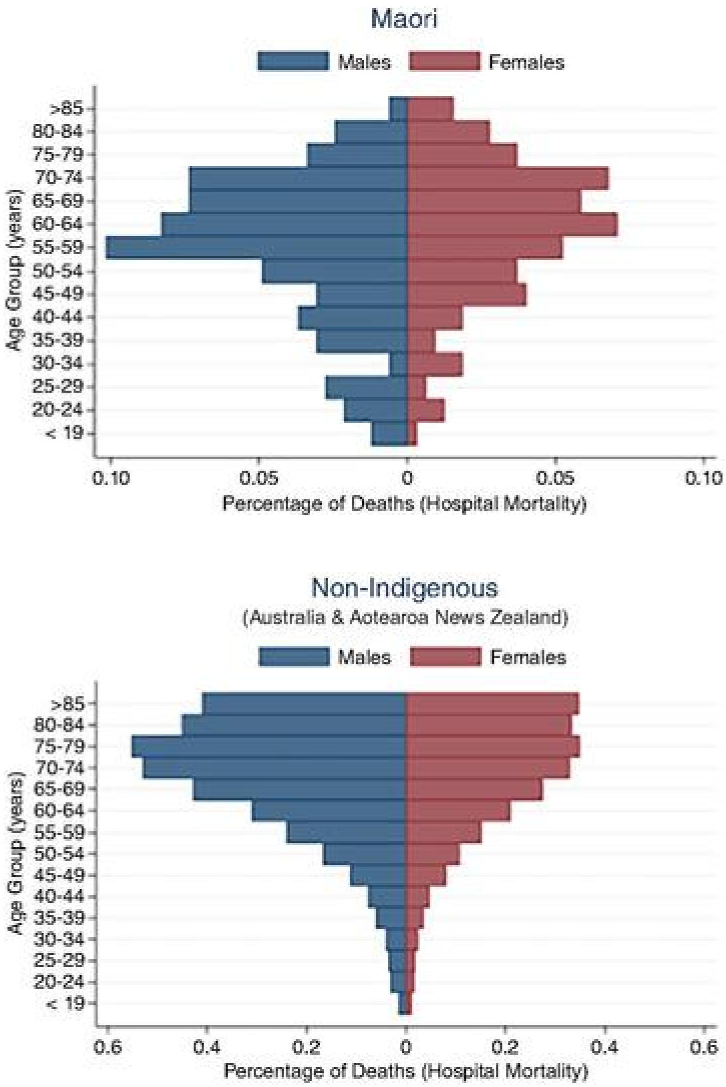


FIG. 87.3 Population pyramid depicting age at death (hospital mortality) for Aboriginal and Torres Strait Island (panel A), Måori (panel B) and non-First Nations critically ill patients. (From Australian and New Zealand Intensive Care Society Centre for Outcome and Resource Evaluation (ANZICS CORE).)

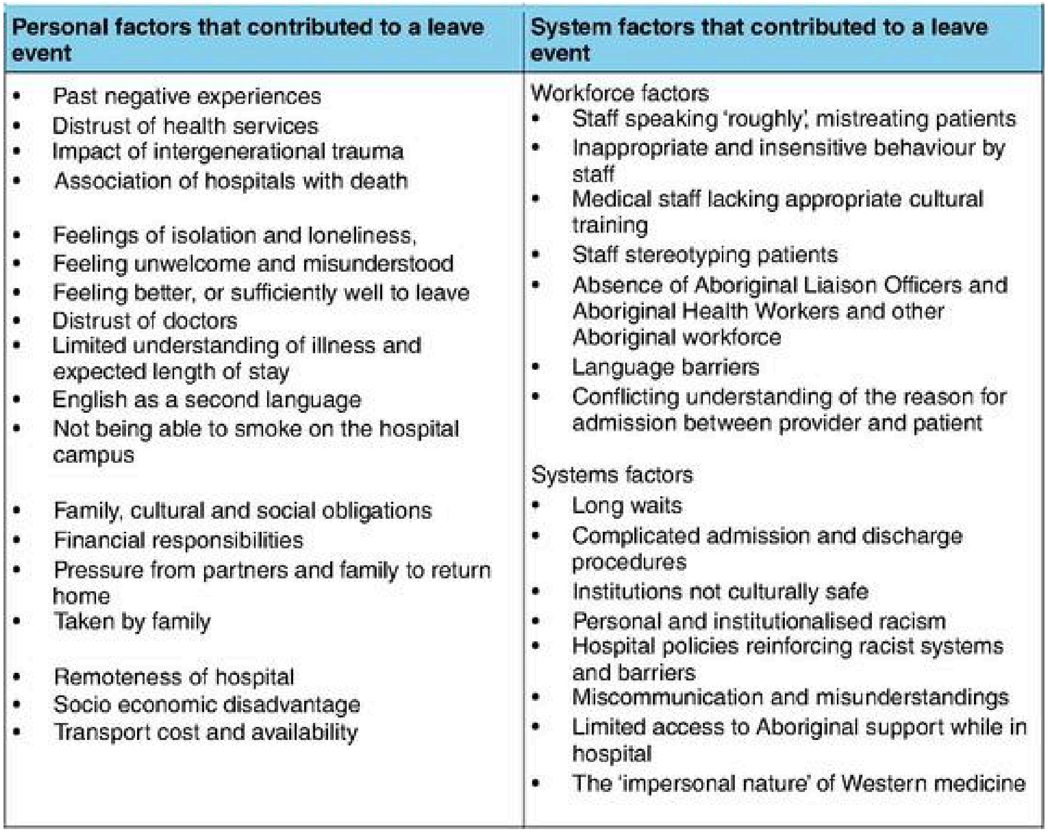

Personal factors that contributed to a leave event	System factors that contributed to a leave event
• Past negative experiences • Distrust of health services • Impact of intergenerational trauma • Association of hospitals with death • Feelings of isolation and loneliness, • Feeling unwelcome and misunderstood • Feeling better, or sufficiently well to leave • Distrust of doctors • Limited understanding of illness and expected length of stay • English as a second language • Not being able to smoke on the hospital campus • Family, cultural and social obligations • Financial responsibilities • Pressure from partners and family to return home • Taken by family • Remoteness of hospital • Socio economic disadvantage • Transport cost and availability	Workforce factors • Staff speaking 'roughly', mistreating patients • Inappropriate and insensitive behaviour by staff • Medical staff lacking appropriate cultural training • Staff stereotyping patients • Absence of Aboriginal Liaison Officers and Aboriginal Health Workers and other Aboriginal workforce • Language barriers • Conflicting understanding of the reason for admission between provider and patient Systems factors • Long waits • Complicated admission and discharge procedures • Institutions not culturally safe • Personal and institutionalised racism • Hospital policies reinforcing racist systems and barriers • Miscommunication and misunderstandings • Limited access to Aboriginal support while in hospital • The 'impersonal nature' of Western medicine

FIG. 87.4 Summary of leave events.

Even allowing for equitable ICU care, data suggest that both the over-representation and long-term outcomes of Māori and Aboriginal and Torres Strait Islander in ICUs are markers of the disease trajectory. The implication is that there is a need to focus our attention on factors that pre-dispose patients to needing ICU level care and in mitigating the heightened risk of mortality after ICU. Critical illness represents only one, late phase of ill-health, therefore, efforts to improve long-term outcomes must also focus on interventions addressing pre-existing health status as well as post-ICU access to supports (so-called social determinants of recovery).[45, 46] An awareness that long-term outcomes for Māori and Aboriginal and Torres Strait Islander critically ill patients are worse than those for non-First Nations patients should prompt intensivists to recognise their responsibility for advocating for improvements in public health and social policy, as well as a commitment to providing culturally safe critical care.[8, 33, 47]

While the approach to discussing end-of-life and death is discussed in the next section, a section on outcomes would not be complete without a brief discussion of organ donation. While it is difficult to generalise the little qualitative work in this space, themes emerging from two Australian studies exploring attitudes to organ donation amongst Aboriginal and Torres Strait Islanders in Western Australia and in Central Australia, were remarkably consistent with themes from a single Aotearoa NZ study. [48 - 50] While organ donation is viewed as a difficult topic (if not culturally taboo) to discuss for both Aboriginal and Torres Strait Islanders and Māori, there appears to be a general acceptance from First Nations community members that it is an important topic to explore. The work from Central Australia in particular highlighted the role of community education – such that the first exposure to organ donation for family is not in the ICU at the bedside of their loved one. Other concepts, such as the interconnectedness of people to the country, and the importance of returning to country (especially during the burial process) need to be considered for both end-of-life considerations and acknowledged in conversations around organ donation. [48 , 49] For these reasons, discussions about end-of-life and organ donation with Aboriginal and Torres Strait Islander and Māori families should be undertaken by clinicians with appropriate expertise.

Caring for the Critically Ill First Nations Patient

Communication

Partnership amongst patients, those that are important to them and intensive care staff demands effective communication. This, in turn, requires both linguistic mutual intelligibility and cultural sensitivity. Interventions designed to improve cultural competency will facilitate communication between First Nations peoples and health workers. [51] However, it is well-recognised that attempts at effective communication frequently fail. Qualitative work from Central Australia suggests that the approach to death and dying practiced by many clinicians is culturally inappropriate. For example, the widely accepted standard of practice in breaking bad news (using unambiguous, non-euphemistic terms such as ‘death’ and ‘dying’ early in the conversation) is seen as confronting and offensive for Central Australian Aboriginal people.[50]

Similarly, the kinship and next of kin models embedded within the Australian and Aotearoa New Zealand legal and health care frameworks may not reflect the next of kin relationships and responsibilities from the perspectives of First Nations people. For Aboriginal people of Central Australia, the primary decision maker for a critically ill patient is unlikely to be the designated next of kin prescribed in the legal framework. Navigating this requires cultural (and linguistic) interpretation, which means drawing on Aboriginal Liaison Officers (ALOs)/Aboriginal Health Practitioners (AHPs)/Hauora Māori service/Kaiarahi (Wayfinder)/Kaiawhina (Maori health worker). Many intensivists would view the inclusion of allied health staff in the ICU team as integral to the good management of a critically ill patient and would insist on having these clinicians as part of the team. It is past time for cultural and linguistic brokers to also be viewed as an indispensable part of this team.

The use of professional interpreters is variable when conversations are had with First Nations patients and their families. As for other linguistically diverse groups, family members are frequently used as informal translators and this frequently risks imprecision and reluctantly accepted responsibilities. Additionally, Aboriginal English has become distinct from standard English in ‘phonology, morphology, syntax, semantics, discourse and pragmatic functions’ and there is significant potential for misunderstanding.[52]

In both countries, terms to describe patients who leave the health care system prior to being seen by a health professional, or who leave against medical advice are in frequent use.[53] These include ‘take own leave’, ‘absconded’, ‘leave at own risk’, ‘self-discharged’, ‘away/absent without leave (AWOL)’ or ‘discharged against medical advice’. These terms are all pejorative and are better described as ‘leave events’ to avoid stigmatising a patient who may choose to leave the health care system for reasons or factors that are poorly understood by clinicians, if they are understood at all.[53,54] It is clear that the health care system needs to better understand the motivations that drive patients to leave the health care system.[55] Aboriginal and Torres Strait Islander patients have leave events at least two and half times the rate of non-Aboriginal and Torres Strait Islander, and there are both individual and systems-based contributors to this. [53] While there has been some work investigating the reasons for leave events, the literature is sparse and highlights how little is known. [56] Family support or visitor policies that better align with cultural responsibilities may assist, particularly as the health care system emerges from the draconian policies that arose during the COVID pandemic. [57-59] Data from South Australia indicates that the long-term mortality of critically ill patients who have a leave event are worse. [42] Given that ‘health service organisation policies are developed within a western biomedical framework that continues to reinforce colonial power structures in Australia which marginalises Aboriginal and Torres Strait Islander people’, this provides one area where critical care may contribute to ‘closing the gap’. [53] The embedding of First Nations clinicians (Aboriginal Health Practitioners/Liaison Officers/Hauora Maori service/Kaiarahi (Wayfinder)/Kaiawhina (Maori health worker)) into daily clinical practice offers the potential to introduce cultural and linguistic familiarity – in other areas of acute medicine such changes in practice have reduced leave events. [27]

Cultural Safety

Medical training from medical school through to specialisation is predominantly taught from within the dominant Western cultural system, and, whilst there has been an increase in formal teachings directed at appreciating cultural safety, clinicians must be aware of their own cultural biases. For culturally and linguistically diverse groups, hospital settings can be a threatening experience. Given intensivists manage the sickest patients in the hospital and communicate with families at a point when they are most vulnerable, practising cultural safety is paramount. Cultural safety ‘requires healthcare professionals and their associated healthcare organisations to examine themselves and the potential impact of their own culture on clinical interactions and healthcare service delivery. This requires individual healthcare professionals and healthcare organisations to acknowledge and address their own biases, attitudes, assumptions, stereotypes, prejudices, structures and characteristics that may affect the quality of care provided. In doing so, cultural safety encompasses a critical consciousness where healthcare professionals and healthcare organisations engage in ongoing self-reflection and self-awareness and hold themselves accountable for providing culturally safe care, as defined by the patient and their communities, and as measured through progress towards achieving health equity. Culturally safe practice obliges healthcare professionals and their associated healthcare organisations to influence healthcare to reduce bias and achieve equity within the workforce and working environment.' [59] Examples of culturally safe practice as it applies to ICU practice are shown in Box 87.1 . [59-62] Training in culturally safe practice has become a compulsory component of both vocational training and ongoing medical education as dictated by regulatory authorities in both countries.

Box 87.1

Fundamentals of culturally safe practice

- Cultural safety is about community and individual empowerment to manage one's own health and social issues. For critical care clinicians (and the healthcare system in which they work) this necessitates examining our own practices and cultural mores to break down barriers to achieving cultural understanding and responsiveness. This requires introspection, time and the space to listen to the voices of others from non-dominant cultural backgrounds. When achieved it empowers healthcare system, clinician and patient allowing outcomes to be optimised, yet the high rates of leave events suggest that there is still substantial work to do in this area. [19]
- In examining their own cultural identity, a clinician delivering care to a person from another culture will recognise that the imposition of their own culture may disadvantage the patient or their family. Culturally safe care recognises this and can only ultimately be recognised as culturally safe by the patient and/or their families. This recognises the power imbalance that exists between clinician

and patient, healthcare system and patient as well as the dominant culture and patient, particularly when critical illness is involved.

- Cultural identity is highly heterogeneous, and the delivery of culturally safe care will not be the same across all geographical areas of practice. Differences will exist depending on the patient's (and their families) location and life experiences (for example being a member of the stolen generation).
- During critical illness, when communication with patients and families are occurring at times of high stress, ensuring clinical care is delivered in a culturally safe way becomes, arguably, the most important. This includes having a knowledge of the language and terms that patients and their families may be offended by, and ensuring that the 'right' family is included – this may not follow the same hierarchical next-of-kin model that is embedded in the dominant culture.

Advocacy, Research and Data Governance

The proportion of Indigenous staff in intensive care teams is substantially less than the proportion of critically ill Indigenous populations admitted into ICUs in Australia or Aotearoa NZ.[7], [8] At the time of writing there are no Aboriginal and Torres Strait Islander intensivists, and only five Māori intensivists. Within the CICM training programme fewer than 1.5% of trainees identify as either Māori or Aboriginal and Torres Strait Islander. Advocating for more First Nations clinicians, including intensivists, nurses and allied health staff and insisting on the presence of First Nations health staff on treating teams is an important first step.

Data is a cultural, strategic and economic resource and the role of indigenous data sovereignty must be acknowledged within any discourse around cultural safety and advocacy. Indigenous data sovereignty describes the right of Indigenous peoples to govern the collection, ownership and application of data about Indigenous communities and peoples which is a key aspect of reconciliation.[63] Yet First Nations people have been isolated from much of the collection of data about ethnic status, its access, analysis and interpretation within the context of the mandated collection this variable within large datasets as well as the collection of this in clinical trials. An intrinsic part of the delivery of culturally safe care means giving all ICU patients the opportunity to be involved in clinical trials if they choose to do so. However, Māori and Aboriginal and Torres Strait Islander patients are under-represented in large tertiary units where the majority of research occurs. It also means ensuring that First Nations people are part of the collection and analysis of their data. For Māori, this means Te Mana Raraunga, a governance body created to provide Māori with sovereignty and governance over their own data. For Aboriginal and Torres Strait Islanders, there is no such peak body overseeing Indigenous data sovereignty.

Small steps have been taken in this direction. The Australian Medical Council, the New Zealand Medical Council and the College of Intensive Care Medicine (CICM) have all constructed position statements on the central role of cultural safety in the delivery of clinical care. [64-66] Further, CICM has established the Indigenous Health Committee which has been integral in the development and implementation of an Indigenous health curriculum for both trainees and fellows of the college.

Conclusions

Māori, Aboriginal and Torres Strait Islander and other First Nations populations have suffered as a result of colonisation and this is reflected in poor health outcomes. There is increasing recognition that an ICU admission should be viewed as part of a healthcare continuum and this is particularly true for disadvantaged populations such as Māori and Aboriginal and Torres Strait Islander peoples. [47] Critical illness is one phase of the disease and is defined not solely by the need for ICU-level support. It reflects a complex interaction between preexisting health status with illness severity. [8], [33], [46] Intensivists must be cognisant of these underlying factors when managing critically ill patients. It behoves intensivists not only to make full use of available health service resources to improve outcomes for First Nations peoples but also to advocate for action to address the inequity which currently exists. Reflection on services, protocols and procedures should regularly have an equity lens applied to it to ensure that barriers to effective and timely care are reduced or eliminated.

Effective communication has always been, and will remain, key to a successful patient journey, never more so than in critical care. When managing First Nations peoples, this can be achieved with the assistance of cultural support services (Aboriginal Liaison Officers/Hauora Maori service/Kaiarahi (Wayfinder)/Kaiawhina (Māori health worker)). Early referral is arguably as important as early antibiotics in sepsis. Clinicians should remain acutely aware of their own cultural biases which may impact on important clinical decisions and patient/family interactions. To emphasise how important this is, education covering cultural safety and effective communication with First Nations peoples is now a mandatory training and professional development requirement for all vocational medical colleges in Australia and Aotearoa New Zealand. Finally, there needs to be a large and sustained effort to attract, and subsequently support, Aboriginal and Torres Strait Islander and Māori clinicians to the exciting and rewarding practice of intensive care, with the goal of creating a workforce that represents them.

It is past time for Intensivists to emerge from within the walls of our ICU and to take action – campaign for and deliver culturally safe care, and advocating for those whose voice is lost in the complex web of our health system. While action may be perceived as symbolic, inclusivity begins with symbolism. Until this is recognised marginalisation will persist and the provision of the highest quality of care for our most vulnerable patients, including critically ill Māori and Aboriginal and Torres Strait Islanders will suffer. Pre-eclampsia, eclampsia and related disorders in pregnancy

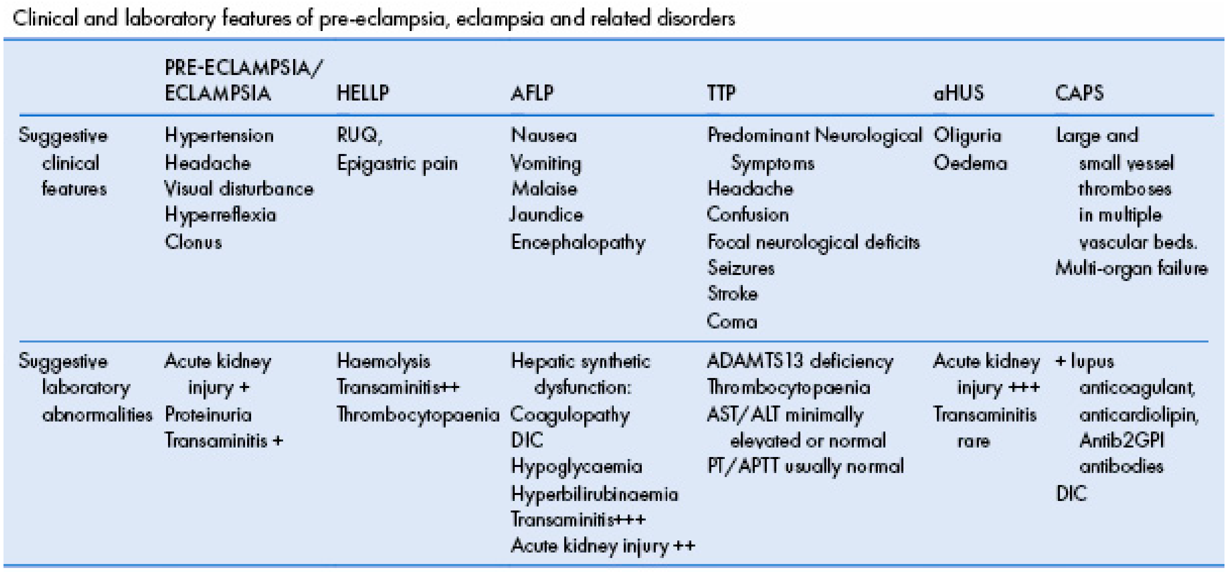
Sadie Callahan, Josephine Gwyneth Laurie and Nai An Lai

Introduction

Pre-eclampsia, eclampsia, haemolysis, elevated liver enzymes and low platelets (HELLP) syndrome, acute fatty liver of pregnancy (AFLP) and pregnancy-associated thrombotic microangiopathies (TMA) represent a spectrum of diseases related to abnormal placentation, imbalance of pro and anti-angiogenic factors, endothelial dysfunction and immune dysregulation that occur in the setting of pregnancy. These complex syndromes share pathophysiological, clinical and laboratory features (Table 88.1). As such they often present clinicians with diagnostic conundrums.

Table 88.1



Clinical and laboratory features of pre-eclampsia, eclampsia and related disorders

	PRE-ECLAMPSIA/ ECLAMPSIA	HELLP	AFLP	TTP	aHUS	CAPS
Suggestive clinical features	Hypertension Headache Visual disturbance Hyperreflexia Clonus	RUQ, Epigastric pain	Nausea Vomiting Malaise Jaundice Encephalopathy	Predominant Neurological Symptoms Headache Confusion Focal neurological deficits Seizures Stroke Coma	Oliguria Oedema	Large and small vessel thromboses in multiple vascular beds. Multi-organ failure
Suggestive laboratory abnormalities	Acute kidney injury + Proteinuria Transaminitis +	Haemolysis Transaminitis++ Thrombocytopaenia	Hepatic synthetic dysfunction: Coagulopathy DIC Hypoglycaemia Hyperbilirubinaemia Transaminitis+++ Acute kidney injury ++	ADAMTS13 deficiency Thrombocytopaenia AST/ALT minimally elevated or normal PT/APTT usually normal	Acute kidney injury +++ Transaminitis rare	+ lupus anticoagulant, anticardiolipin, Antib2GPI antibodies DIC

AFLP , acute fatty liver of pregnancy; *aHUS* , atypical haemolytic uraemic syndrome; *ALT* , alanine transaminase; *APTT* , activated partial thromboplastin time; *AST* , aspartate transaminase; *CAPS* , catastrophic antiphospholipid syndrome; *DIC* , disseminated intravascular coagulation; *HELLP* , haemolysis elevated liver enzymes low platelets syndrome; *PT* , prothrombin time; *RUQ* , right upper quadrant; *TTP* , thrombotic thrombocytopaenic purpura.

Multidisciplinary and multi-specialty collaboration involving intensive care, obstetrics, obstetric medicine, anaesthesia, neonatology and other relevant specialties such as haematology and nephrology is crucial to optimise maternal and fetal outcomes. Importantly, diagnostic uncertainties should not delay the initiation of supportive care in critically unwell pregnant patients.

Salient clinical features, pathophysiological mechanisms and management principles of pre-eclampsia, eclampsia and related disorders will be outlined in this chapter. Other obstetric emergencies including obstetric haemorrhage, trauma, sepsis, septic shock and principles of resuscitation will be covered in Chapter 89 .

PRE-ECLAMPSIA AND ECLAMPSIA

Pre-eclampsia

Pre-eclampsia is a multisystem disorder defined as new onset of hypertension (systolic blood pressure [SBP] ≥140 mm Hg and/or diastolic blood pressure [DBP] ≥90 mm Hg), at or after 20 weeks gestation, with signs of new-onset organ dysfunction including the fetus as an end organ. [1] Traditional definition of pre-eclampsia, that is, new-onset hypertension and proteinuria at 20 weeks or more of gestation has been superseded in recognition of multisystem involvement in this condition. [2] Pre-eclampsia occurs in 4.6% of pregnancies worldwide and can present with a spectrum of signs and symptoms. [3]

Pathogenesis, Risk Factors and Biomarkers

Pre-eclampsia has a complex pathophysiology that starts with abnormal placentation early in the first trimester. This results in an imbalance in pro- and anti-angiogenic factors leading to endothelial dysfunction, a vasoconstrictive state, inflammation, oxidative stress and susceptibility to the development of microthrombi. [4], [5]

The following factors have been identified as conferring high risk for developing pre-eclampsia [6]:

- Previous hypertensive disorder during pregnancy
- Chronic kidney disease or kidney impairment
- Multi-fetal gestation
- Pre-existing chronic hypertension
- Pre-existing Type 1 or Type 2 diabetes mellitus
- Autoimmune disorders, for example systemic lupus erythematosus (SLE) and antiphospholipid syndrome (APS)

The following confer moderate risk for developing pre-eclampsia (2 or more risk factors required to be considered high risk) [6]:

- Advanced maternal age (>40)
- Obesity (body mass index [BMI] ≥35)
- Nulliparity
- Family history of pre-eclampsia
- Interpregnancy interval of >10 years
- Use of assisted reproductive technologies
- SBP >130 mm Hg and/or DBP >80 mm Hg

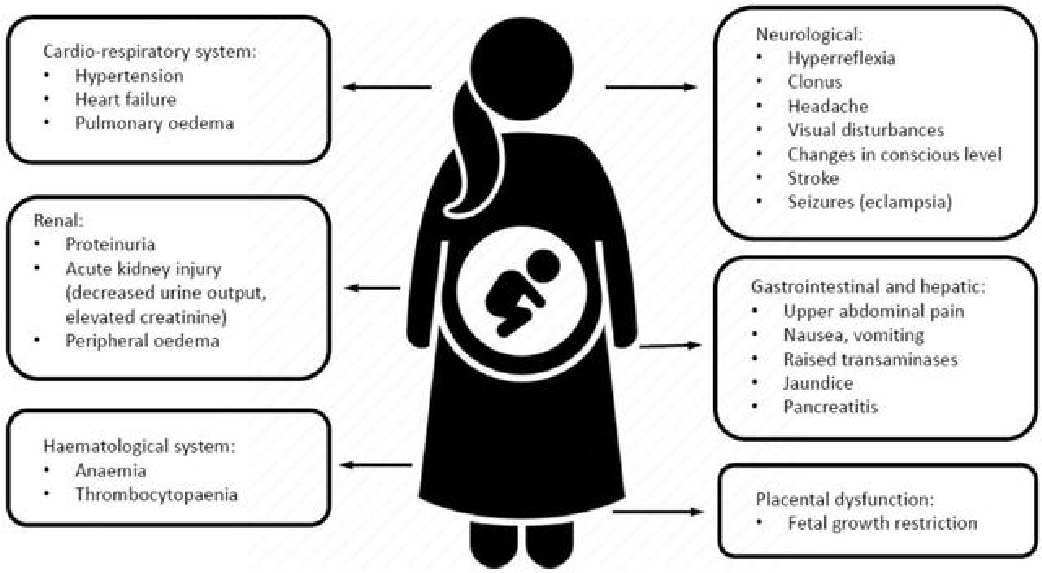
Recently the combination of maternal clinical risk factors, sonographic features of increased uterine artery resistance (e.g. uterine artery pulsatility index [UtA-PI] and uterine artery resistive index [UtA-RI]) and serum biomarkers of angiogenesis (e.g. the anti-angiogenic factor, soluble fms-like tyrosine kinase 1 [sFlt-1], the pro-angiogenic factor, placental growth factor [PlGF] and the sFlt-1/PlGF ratio) have been shown to improve the accuracy of identifying women at risk of developing pre-eclampsia.[6,7] In particular, an sFlt-1:PlGF ratio of 38 or lower has been shown to rule out pre-eclampsia with a negative predictive value of 99.3%.[8] However, sonographic expertise and resources to measure circulating markers of angiogenesis are not widely available thus their routine use has not been universally recommended by societal guidelines.[6,9]

Prevention of Pre-eclampsia

Aspirin 150 mg/day is recommended for women at high risk of developing pre-eclampsia. It should ideally be commenced prior to 16 weeks gestation and continue to at least 34 weeks of gestation.[6] Exact timing of aspirin cessation should be individualised through an informed, shared decision-making process with the patient. Supplemental calcium is recommended for pregnant women with low dietary calcium intake. Current evidence does not support the use of other supplements and pharmacological agents in the prevention of pre-eclampsia including metformin, omega-3 fatty acids, vitamin D, statins and antioxidants (vitamin C and vitamin E).[6]

Clinical Features

Clinical features of pre-eclampsia are shown in Fig. 88.1 .



Cardio-respiratory system:
• Hypertension
• Heart failure
• Pulmonary oedema
Renal:
• Proteinuria
• Acute kidney injury (decreased urine output, elevated creatinine)
• Peripheral oedema
Haematological system:
• Anaemia
• Thrombocytopaenia
Neurological:
• Hyperreflexia
• Clonus
• Headache
• Visual disturbances
• Changes in conscious level
• Stroke
• Seizures (eclampsia)
Gastrointestinal and hepatic:
• Upper abdominal pain
• Nausea, vomiting
• Raised transaminases
• Jaundice
• Pancreatitis
Placental dysfunction:
• Fetal growth restriction

The illustration shows a pregnant woman. The different disorders and symptoms of pre-eclampsia are listed around her. They are Cardio-respiratory system: Hypertension, heart failure, pulmonary oedema; Neurological: Hyperreflexia, clonus, headache, visual disturbances, changes in conscious level, stroke, seizures in eclampsia; Renal: Proteinuria, acute kidney injury with decreased urine output and elevated creatinine, peripheral oedema; Gastrointestinal and hepatic: Upper abdominal pain, nausea, vomiting, raised transaminases, jaundice, pancreatitis; Haematological system: Anaemia, thrombocytopaenia; Placental dysfunction: Fetal growth restriction.

FIG. 88.1 Clinical features of pre-eclampsia (adapted from [10]).

Management

Delivery of the fetus is the definitive management for pre-eclampsia and eclampsia. Shared decision making about the timing of delivery, with input from a multidisciplinary team, including obstetrics, obstetric medicine, neonatology, intensive care and anaesthetics, is crucial. The mode of delivery is as obstetrically indicated.[11, 12]

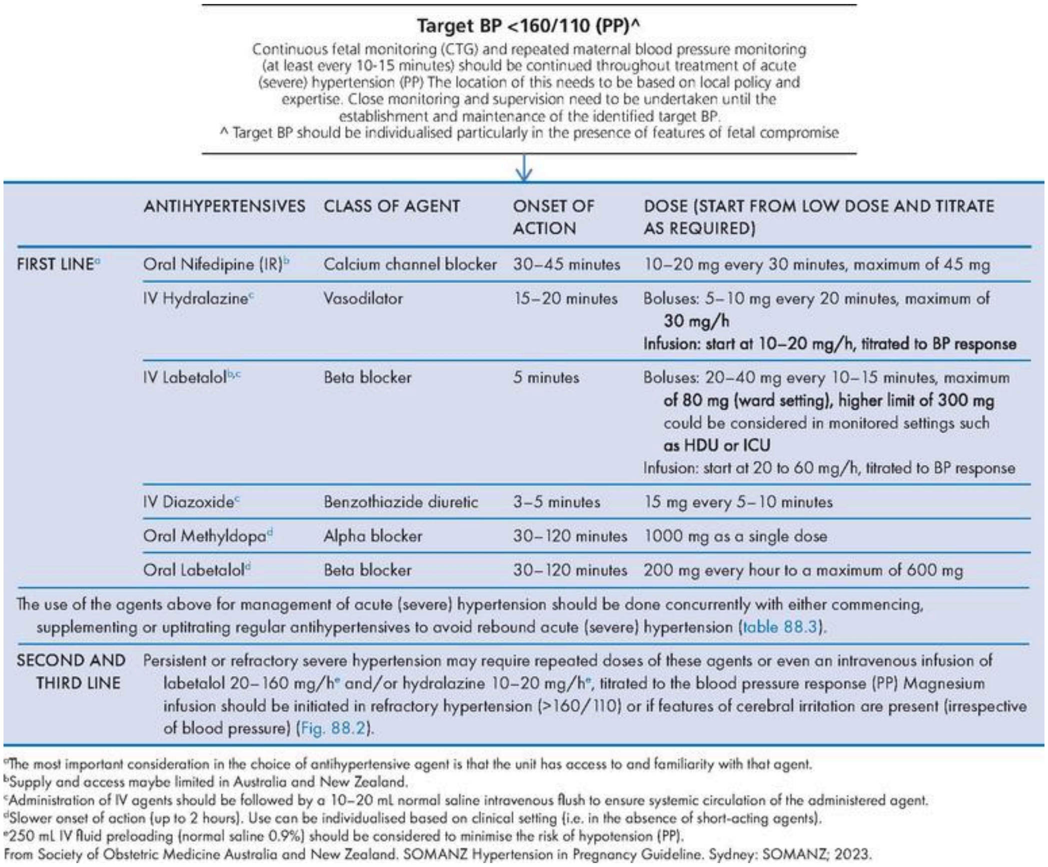
Supportive care should be provided antepartum, and during the immediate post-partum period, focusing on:

- control of blood pressure (BP),
- prevention of seizures (eclampsia) with magnesium sulphate,
- maintenance of placental perfusion,
- monitoring of fetal wellbeing,
- prevention of complications.

Control of Blood Pressure

Acute, severe hypertension should be treated to a target of SBP <160 mm Hg and DBP <110 mm Hg to prevent maternal neurological and cardiopulmonary complications.[1] Further control of BP should be gradual and sustained while preserving maternal end-organ and placental perfusion.

Commonly used first-line antihypertensive agents include labetalol (IV/PO), hydralazine (IV), nifedipine IR (PO) and methyldopa (PO). Second-line therapy includes infusions of labetalol or hydralazine.[13] Fig. 88.2 outlines the initial doses and time to onset of pharmacological action of first- and second-line agents. Sodium nitroprusside (duration should be less than 4 hours to avoid fetal cyanide poisoning) or glyceryl trinitrate (GTN) infusion may be considered in a hypertensive emergency refractory to first- and second-line therapies.



Target BP <160/110 (PP)^

Continuous fetal monitoring (CTG) and repeated maternal blood pressure monitoring (at least every 10-15 minutes) should be continued throughout treatment of acute (severe) hypertension (PP) The location of this needs to be based on local policy and expertise. Close monitoring and supervision need to be undertaken until the establishment and maintenance of the identified target BP.

^ Target BP should be individualised particularly in the presence of features of fetal compromise

	ANTIHYPERTENSIVES	CLASS OF AGENT	ONSET OF ACTION	DOSE (START FROM LOW DOSE AND TITRATE AS REQUIRED)
FIRST LINE[a]	Oral Nifedipine (IR)[b]	Calcium channel blocker	30–45 minutes	10–20 mg every 30 minutes, maximum of 45 mg
	IV Hydralazine[c]	Vasodilator	15–20 minutes	Boluses: 5–10 mg every 20 minutes, maximum of **30 mg/h** **Infusion: start at 10–20 mg/h, titrated to BP response**
	IV Labetalol[b,c]	Beta blocker	5 minutes	Boluses: 20–40 mg every 10–15 minutes, maximum **of 80 mg (ward setting), higher limit of 300 mg** could be considered in monitored settings such **as HDU or ICU** Infusion: start at 20 to 60 mg/h, titrated to BP response
	IV Diazoxide[c]	Benzothiazide diuretic	3–5 minutes	15 mg every 5–10 minutes
	Oral Methyldopa[d]	Alpha blocker	30–120 minutes	1000 mg as a single dose
	Oral Labetalol[d]	Beta blocker	30–120 minutes	200 mg every hour to a maximum of 600 mg
The use of the agents above for management of acute (severe) hypertension should be done concurrently with either commencing, supplementing or uptitrating regular antihypertensives to avoid rebound acute (severe) hypertension (table 88.3).				
SECOND AND THIRD LINE	Persistent or refractory severe hypertension may require repeated doses of these agents or even an intravenous infusion of labetalol 20–160 mg/h[e] and/or hydralazine 10–20 mg/h[e], titrated to the blood pressure response (PP) Magnesium infusion should be initiated in refractory hypertension (>160/110) or if features of cerebral irritation are present (irrespective of blood pressure) (Fig. 88.2).			

[a] The most important consideration in the choice of antihypertensive agent is that the unit has access to and familiarity with that agent.
[b] Supply and access maybe limited in Australia and New Zealand.
[c] Administration of IV agents should be followed by a 10–20 mL normal saline intravenous flush to ensure systemic circulation of the administered agent.
[d] Slower onset of action (up to 2 hours). Use can be individualised based on clinical setting (i.e. in the absence of short-acting agents).
[e] 250 mL IV fluid preloading (normal saline 0.9%) should be considered to minimise the risk of hypotension (PP).

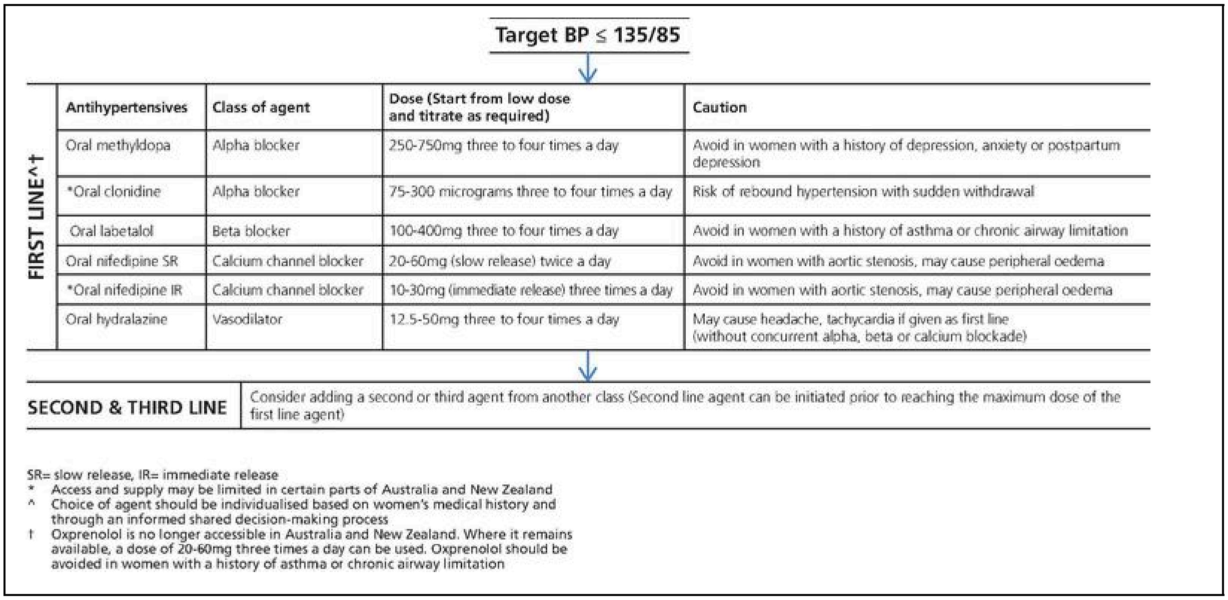
From Society of Obstetric Medicine Australia and New Zealand. SOMANZ Hypertension in Pregnancy Guideline. Sydney: SOMANZ; 2023.

FIG. 88.2 Management of acute hypertension in pre-eclampsia.

Given there is no strong evidence to recommend one antihypertensive over the other, the most important consideration is access to, and familiarity with, the agent. Likewise, in the post-partum period, there is insufficient evidence to recommend specific drugs for the ongoing treatment of hypertension. Therefore ongoing antihypertensive treatment should be individualised (Table 88.2).

Table 88.2

Management of chronic, gestational and non-severe hypertension preeclampsia (Adapted from Society of Obstetric Medicine Australia and New Zealand. SOMANZ Hypertension in Pregnancy Guideline. Sydney: SOMANZ; 2023.)



Target BP ≤ 135/85

	Antihypertensives	Class of agent	Dose (Start from low dose and titrate as required)	Caution
FIRST LINE^†	Oral methyldopa	Alpha blocker	250-750mg three to four times a day	Avoid in women with a history of depression, anxiety or postpartum depression
	*Oral clonidine	Alpha blocker	75-300 micrograms three to four times a day	Risk of rebound hypertension with sudden withdrawal
	Oral labetalol	Beta blocker	100-400mg three to four times a day	Avoid in women with a history of asthma or chronic airway limitation
	Oral nifedipine SR	Calcium channel blocker	20-60mg (slow release) twice a day	Avoid in women with aortic stenosis, may cause peripheral oedema
	*Oral nifedipine IR	Calcium channel blocker	10-30mg (immediate release) three times a day	Avoid in women with aortic stenosis, may cause peripheral oedema
	Oral hydralazine	Vasodilator	12.5-50mg three to four times a day	May cause headache, tachycardia if given as first line (without concurrent alpha, beta or calcium blockade)

SECOND & THIRD LINE	Consider adding a second or third agent from another class (Second line agent can be initiated prior to reaching the maximum dose of the first line agent)

SR= slow release, IR= immediate release

* Access and supply may be limited in certain parts of Australia and New Zealand

^ Choice of agent should be individualised based on women's medical history and through an informed shared decision-making process

† Oxprenolol is no longer accessible in Australia and New Zealand. Where it remains available, a dose of 20-60mg three times a day can be used. Oxprenolol should be avoided in women with a history of asthma or chronic airway limitation

Prevention of Eclampsia

There is strong evidence that magnesium sulphate ($MgSO_4$) reduces the risk of development of eclampsia and recurrent eclampsia, and it should be used as first-line therapy. [14] The exact anti-epileptic mechanism of magnesium is unclear. Stimulation of N-methyl-d-aspartate (NMDA) receptors by neurotransmitters such as glutamate is thought to contribute towards seizure activities when neuronal networks are over-activated. Magnesium is thought to prevent and control eclamptic seizures by inhibiting NMDA receptors while also contributing towards cerebral vasodilatation through the activation of nitric oxide synthases. Magnesium is also a calcium antagonist and is thought to play a role in regulating the cerebral endothelium, reducing inflammation, mitigating cerebral oedema and seizure activity. [15]

Current guidelines [1], [6], [16] suggest the use of prophylactic $MgSO_4$ in patients with

- Persistent severe hypertension ≥160/110 mm Hg.
- Features of neurological irritability, including ongoing or recurring severe headache, visual disturbances, clonus and hyperreflexia.

The recommended dosing regimen is 4 g of IV $MgSO_4$ followed by maintenance at 1 g/h. [6], [14] The infusion is usually continued for 24 hours post-delivery (or 24 hours total if commenced post-partum) or from the time of the last seizure. It may be reasonable to extend the infusion beyond 24 hours if there are no signs of clinical improvement.

Although monitoring of serum magnesium levels is not generally recommended for all obstetric patients receiving magnesium infusions, it is prudent and encouraged in the critically ill population admitted to the ICU. The recommended therapeutic range for plasma magnesium concentration is 2–3.5 mmol/L. [17] Frequency of monitoring of plasma levels will vary depending on the clinical scenario.

In the event of eclampsia, consider a further dose of 2–4 g of IV $MgSO_4$ over 15 mins and then increasing the infusion rate as per plasma magnesium levels.

Magnesium is excreted rapidly by the kidneys. With normal renal function, the half-life is 4 hours and 90% of the dose is excreted 24 hours post cessation of the infusion. Caution should be shown in patients with renal impairment, where infusion rates should be guided by plasma magnesium levels, and in patients with hypocalcaemia. Symptoms and signs of hypermagnesaemia include absent deep tendon reflexes, muscle weakness, slurred speech, double vision, bradypnoea and bradycardia. [18-20] $MgSO_4$ infusion is contraindicated in patients with myasthenia gravis as it may precipitate a myasthenic crisis.

Monitoring and Supportive Care of the Pre-Eclamptic Patient

Intra-arterial BP monitoring is usually indicated in patients with pre-eclampsia/eclampsia admitted to ICU. SBP and DBP remain the target variables, not mean arterial pressure (MAP) in this clinical scenario. The use of transthoracic echo can provide valuable, non-invasive assessments of ventricular function and fluid responsiveness. Fluid balance can be difficult to assess clinically in these patients and care must be taken to avoid hyper or hypovolemia as pre-eclamptic patients are usually intravascularly deplete but poorly tolerant of volume overload. Use of DVT prophylaxis needs to be individualised. Emotional care of the family and psychological support are crucial elements of holistic care.

Monitoring and Protection of Fetal Wellbeing

Close consultation with the obstetric and obstetric medical teams is essential regarding the modality and frequency of monitoring of fetal wellbeing, including CTG and ultrasound, and fetal protective treatments.

Corticosteroids may be recommended for fetal lung maturation in patients at risk of preterm delivery (especially <34 weeks). There is strong evidence to support the use of betamethasone or dexamethasone to reduce neonatal morbidity and mortality in preterm infants.[21]

Additionally, $MgSO_4$ may be recommended for fetal neuroprotection. Current evidence strongly recommends its use in patients at risk of preterm delivery <30 weeks. Treatment may also be considered for gestations 30–34 weeks.[22,23] Dosage is the same as for the prevention and management of eclampsia. However, if fetal neuroprotection is the only indication for $MgSO_4$ then the infusion should be ceased once the baby is delivered.

Prognosis

Pre-eclampsia is an uncommon cause of maternal mortality in the developed world but does cause significant morbidity such as stroke, acute pulmonary oedema, eclamptic seizures, posterior reversible encephalopathy syndrome (PRES) and acute kidney injury.[4,24] The fetus is at risk of growth restriction, placental abruption, stillbirth and preterm birth and its sequelae.

Although recovery from the organ dysfunction of pre-eclampsia usually occurs within approximately 6 weeks, patients are at increased risk of developing hypertension, cardiovascular disease including ischaemic heart disease, stroke and heart failure, and kidney disease later in life. They also have an increased risk of early all-cause mortality and some cause-specific mortality, specifically, ischaemic heart disease, stroke and diabetes. [25-28]

Eclampsia

Eclampsia is defined as new onset generalised, focal or multifocal seizures in the setting of a hypertensive disorder of pregnancy in the absence of another cause. [29] It is a clinical manifestation at the severe end of the pre-eclampsia spectrum and may be the first presenting symptom in some patients. Approximately 1% to 2% of patients with pre-eclampsia develop eclampsia. It is rare in developed countries. [29] Approximately 20% of cases occur in the post-partum period. [30], [31]

Pathophysiology [29], [32]

The precise cause of eclampsia is unclear. However, several contributory mechanisms have been proposed. Firstly, a rapid rise in BP to above 150 mm Hg overcomes cerebral autoregulatory mechanisms resulting in increased cerebral blood flow, hyper-perfusion, endothelial dysfunction and vasogenic and/or cytotoxic cerebral oedema.

Secondly, hypertension may trigger an exaggerated response from central nervous system (CNS) autoregulatory mechanisms resulting in cerebral vasospasm, hypoperfusion, ischaemia, endothelial dysfunction, reperfusion injury, vasogenic and/or cytotoxic cerebral oedema.

Additionally, eclampsia can develop when SBP is less than 150–160 mm Hg indicating that it is not BP level alone that drives seizures, and that endothelial dysfunction may have a primary role. Finally, stimulation of NMDA receptors by glutamate and release of pro-inflammatory mediators are also thought to be contributory.

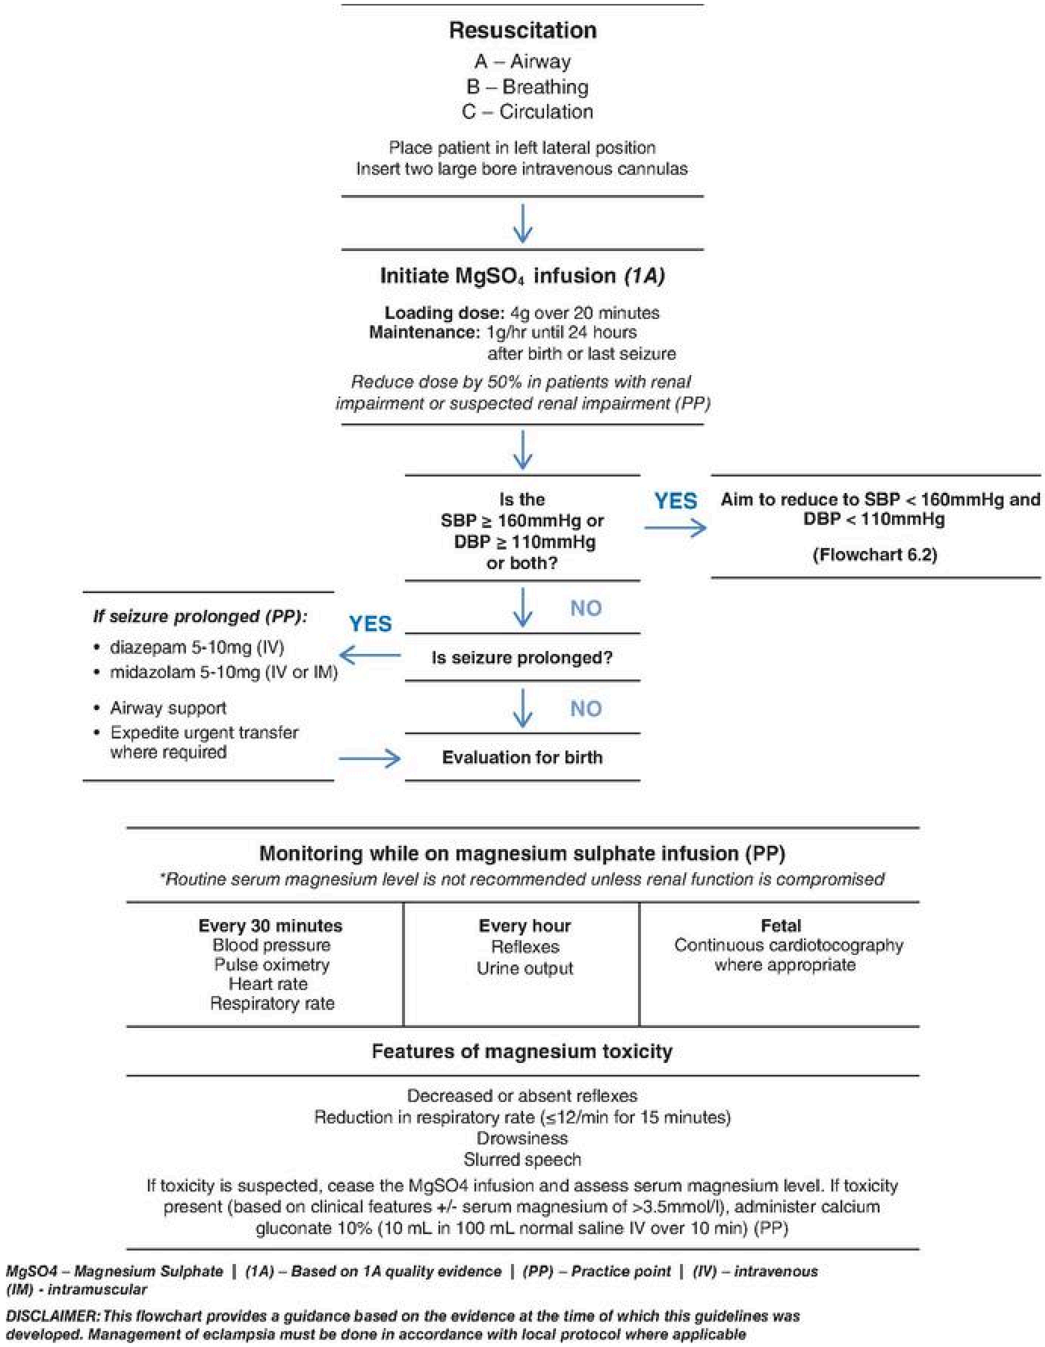
Diagnosis

Eclampsia is a clinical diagnosis, made on the basis of a seizure, most commonly generalised, typically in a patient with a hypertensive disorder of pregnancy (pre-eclampsia, HELLP and gestational hypertension). It is important to consider other causes of seizure including epilepsy, intracranial haemorrhage, cerebral venous sinus thrombosis, and less commonly; CNS infection, thrombotic thrombocytopaenic purpura (TTP), amniotic fluid embolism as well as primary and secondary intracranial tumours.[29]

A computerised tomography (CT) scan of the brain with CT venogram should be considered after the patient is stabilised to exclude intracranial haemorrhage and cerebral venous sinus thrombosis. Magnetic resonance imaging (MRI) may be indicated to diagnose posterior reversible encephalopathy syndrome (PRES), a clinico-radiological syndrome characterised by neurological deficits (predominantly visual) and white matter vasogenic oedema,[33] which could be a manifestation of severe pre-eclampsia.[29]

Management

Resuscitation of a pregnant patient with eclamptic seizures follows the principles of resuscitation outlined in the chapter on obstetric emergencies. Fig. 88.3 is a flow diagram that guides clinicians in managing pregnant patients with eclampsia. Prompt establishment of airway patency, avoiding aspiration, ensuring adequate oxygenation and ventilation as well as assessment and support of maternal circulation should be the priorities. $MgSO_4$ should be administered early with a loading dose of 4 g IV followed by 1 g/h until 24 hours after delivery or last seizure.[6] An additional dose of 2 to 4 g can be given if the patient develops seizures while still on a $MgSO_4$ infusion. Conventional anticonvulsants, such as benzodiazepines, phenytoin and levetiracetam, can be considered when there are recurrent seizures despite therapeutic serum magnesium levels, or when $MgSO_4$ is contraindicated. BP reduction is vital for neuroprotection, targeting SBP <160 mm Hg and DBP <110 mm Hg. Maternal vital signs, fetal wellbeing and signs of magnesium toxicity should be monitored closely.[6, 29]



Resuscitation

A – Airway
B – Breathing
C – Circulation

Place patient in left lateral position
Insert two large bore intravenous cannulas

Initiate $MgSO_4$ infusion *(1A)*

Loading dose: 4g over 20 minutes
Maintenance: 1g/hr until 24 hours after birth or last seizure

Reduce dose by 50% in patients with renal impairment or suspected renal impairment (PP)

Is the SBP ≥ 160mmHg or DBP ≥ 110mmHg or both?

YES → **Aim to reduce to SBP < 160mmHg and DBP < 110mmHg**

(Flowchart 6.2)

NO

Is seizure prolonged?

YES →

If seizure prolonged (PP):

- diazepam 5-10mg (IV)
- midazolam 5-10mg (IV or IM)

- Airway support
- Expedite urgent transfer where required

NO

Evaluation for birth

Monitoring while on magnesium sulphate infusion (PP)

**Routine serum magnesium level is not recommended unless renal function is compromised*

Every 30 minutes	**Every hour**	**Fetal**
Blood pressure Pulse oximetry Heart rate Respiratory rate	Reflexes Urine output	Continuous cardiotocography where appropriate

Features of magnesium toxicity

Decreased or absent reflexes
Reduction in respiratory rate (≤12/min for 15 minutes)
Drowsiness
Slurred speech

If toxicity is suspected, cease the MgSO4 infusion and assess serum magnesium level. If toxicity present (based on clinical features +/- serum magnesium of >3.5mmol/l), administer calcium gluconate 10% (10 mL in 100 mL normal saline IV over 10 min) (PP)

MgSO4 – Magnesium Sulphate | (1A) – Based on 1A quality evidence | (PP) – Practice point | (IV) – intravenous (IM) - intramuscular

DISCLAIMER: This flowchart provides a guidance based on the evidence at the time of which this guidelines was developed. Management of eclampsia must be done in accordance with local protocol where applicable

The clinical flowchart outlines the protocol for magnesium sulfate (Mg S O 4) infusion. It begins with resuscitation steps labelled A for airway, B for breathing, and C for circulation, including placing the patient in the left lateral position and inserting two large intravenous cannulas. Next is initiation of Mg S O 4 infusion with a loading dose of 4 grams over 20 minutes and a maintenance dose of 1 gram per hour until 24 hours after delivery or last seizure. A dose reduction is noted for patients with renal impairment. The flowchart then checks if systolic blood pressure is greater than or equal to 160 millimetres of mercury or diastolic blood pressure is greater than or equal to 110 millimetres of mercury. If yes, the aim is to reduce B P using a linked flow chart. If no, the next decision point assesses whether seizures are prolonged. If seizures are prolonged, recommended drugs include diazepam or midazolam, with airway support and urgent transfer if needed. If not, the patient is evaluated for delivery. A section below describes monitoring steps during magnesium infusion, such as blood pressure, pulse, reflexes, respiratory rate every 30 minutes, urine output and reflexes every 4 hours, and continuous fetal monitoring. A final section outlines features of magnesium toxicity, such as reduced or absent reflexes, respiratory depression, drowsiness, and blurred speech. Instructions are included for stopping the infusion and administering calcium gluconate if toxicity is suspected. A footnote explains dosage routes, and a disclaimer states that the flowchart is a guideline based on evidence and local policies.

HELLP Syndrome [34, 35]

HELLP syndrome complicates approximately 0.5%–0.9% of all pregnancies. It is also a syndrome of placental dysfunction and is associated with increased rates of maternal morbidity and mortality.

Pathogenesis and Pathophysiology

The exact pathogenesis of HELLP is unclear. There is similarity to pre-eclampsia in terms of the central role of abnormal placentation, imbalance of pro and anti-angiogenic factors, endothelial dysfunction and immune dysregulation. On the other hand, the reasons for greater hepatic inflammation and greater consumptive activation of the coagulation system in HELLP are unknown.

Clinical Features

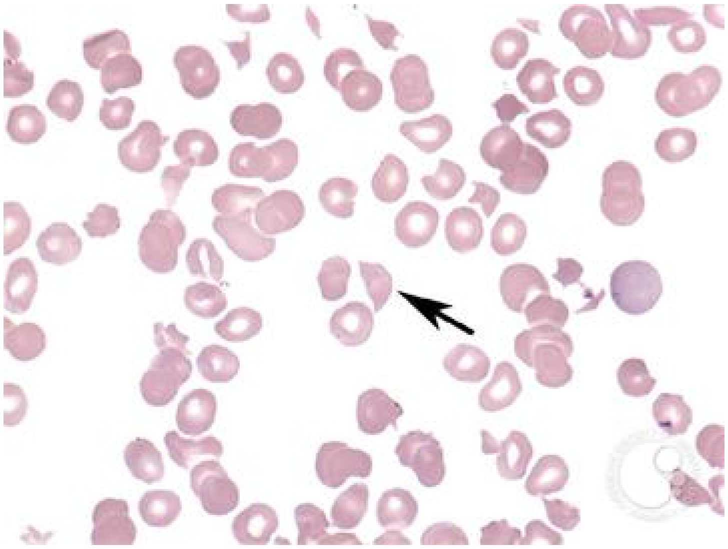
Abdominal pain, typically in the right upper quadrant (RUQ) or epigastrium, is the most common symptom. It is often associated with tenderness to palpation. Non-specific symptoms of nausea, vomiting and malaise are also common. Hypertension is also common, but not essential to make the diagnosis. Proteinuria may be present.

The onset of HELLP may be insidious and the patient may be critically unwell on presentation with complications including placental abruption, hepatic subcapsular or intraparenchymal haematoma.

Diagnosis

For the diagnosis of HELLP to be made, all of the following must be present:

- microangiopathic haemolysis: the presence of schistocytes on blood film (Fig. 88.4)
- thrombocytopaenia
- elevated transaminases



The microscopic image of a blood smear shows numerous red blood cells with noticeable shape variations. Most cells appear pale and irregular, with some having central pallor. In the centre of the image, an arrow points to a red blood cell with two distinct, evenly spaced, rounded projections on its surface, giving it a helmet-like appearance. Scattered among the red blood cells are occasional small platelets and a single large white blood cell visible on the right side. The cells are spread throughout the field.

FIG. 88.4 Schistocytes on a blood film.

Management

Management principles include:

- Maternal stabilisation
- Planning for delivery
- Management of complications

- Other supportive care.

Delivery of the fetus is the definitive treatment for HELLP. Exact timing of delivery depends on the clinical scenario and a patient-centred decision will be made in consultation with the obstetric and obstetric medicine teams. Indications for $MgSO_4$ infusion are the same as for pre-eclampsia, namely persistent severe hypertension ≥160/110 mm Hg or features of neurological irritability including ongoing or recurring severe headache, visual disturbances, clonus and hyperreflexia. Patients with persistent and severe abdominal pain or significantly increased transaminases should be investigated for hepatic bleeding. Ultrasound is an appropriate initial imaging modality. CT scan or MRI may be indicated if further information is required to guide clinical decision making. An expanding or ruptured haematoma with intraperitoneal extension is a life-threatening complication. The mother should be resuscitated with blood and fluid to restore circulating volume, platelets and clotting factors should be replaced and haemodynamic support provided. Prompt delivery should be arranged. Experienced hepatobiliary surgical team should be engaged early, prior to delivery during the stabilisation period.

Prognosis

Maternal laboratory parameters may worsen for 48 hours post-delivery. However, improvement in biochemistry and platelet count are expected by day 4 post-partum. Despite the severity of maternal complications, with appropriate treatment, most patients recover well without significant long-term sequelae. Developing HELLP in one pregnancy does increase the risk of a patient developing a hypertensive disorder of pregnancy in subsequent pregnancies.

Acute Fatty Liver of Pregnancy [36-38]

Acute fatty liver of pregnancy (AFLP) is a mitochondrial hepatopathy that may result in fulminant hepatic failure and is associated with significant maternal mortality and morbidity. It is a rare condition, affecting 5–30 per 100,000 pregnancies.

Pathogenesis

AFLP develops due to a defect in mitochondrial beta-oxidation of fatty acids. This results in hepatic microvascular steatosis. The most common defect is gene mutation in long-chain 3-hydrocyacyl-CoA dehydrogenase/mitochondrial trifunctional protein (LCHAD/MTP). Other gene mutations have also been reported; however, there are many case reports of AFLP without an associated detectable gene mutation.

Clinical Features and Diagnosis

Patients with AFLP present critically unwell with prominent initial symptoms of nausea, vomiting, abdominal pain and malaise. Patients may develop signs and symptoms of fulminant liver failure including encephalopathy, ascites, jaundice, hypoglycaemia, DIC and hyperlactataemia. Acute kidney injury (AKI) is common. Polydipsia and polyuria may also occur, likely due to decreased levels of arginine vasopressin.

The Swansea criteria are used to aid diagnosis. The presence of six or more abnormal variables had a positive predictive value of 85% and negative predictive value of 100% for finding micro-vesicular steatosis when applied to a group of patients with suspected AFLP who received a liver biopsy.

Swansea criteria:

- Signs and symptoms
  - Vomiting
  - Abdominal pain
  - Polydipsia/polyuria
  - Encephalopathy
- Laboratory findings
  - Elevated bilirubin
  - Hepatic synthetic dysfunction

        - Hypoglycaemia
        - Coagulopathy
    - Elevated transaminases
    - Acute kidney injury
    - Leucocytosis
    - Elevated ammonia
    - Elevated urate
    - Transient diabetes insipidus (DI)
- Imaging: Ascites or hyperechoic liver on ultrasound scan
- Histology: Micro-vesicular steatosis on liver biopsy (biopsy is rarely performed)

Management

Once the diagnosis of AFLP is made, a plan must be made for the delivery of the fetus. Maternal care is otherwise supportive consisting of monitoring for, and treatment of, complications including encephalopathy, hypoglycaemia, coagulopathy and AKI. Patients with signs of liver failure should be referred to/discussed with a liver transplant centre. Requirement for liver transplant is rare but has been reported. Multidisciplinary input is essential and many of these patients will require ICU care.

Prognosis

Major causes of morbidity and mortality are liver failure, haemorrhage, acute renal failure. Maternal mortality has decreased significantly due to better recognition, earlier diagnosis and advances in critical care. Transaminitis usually begins to improve within days following delivery. However hepatic synthetic function may take longer to recover. It is expected that liver functions will eventually return to normal. There are minimal data to inform long-term outlook of AFLP. The rate of recurrence of AFLP in subsequent pregnancies is unknown but recurrence has been reported, even in the absence of detectable genetic mutations.

It may be very difficult to distinguish between pre-eclampsia, HELLP and AFLP. However, the management principles are consistent across the conditions, prompt delivery, control of blood pressure, consideration of magnesium, monitoring for and management of complications and organ failures. Treatment should not be delayed while attempting to make a definitive diagnosis.

Thrombotic Microangiopathies [39]

Thrombotic microangiopathy (TMA) is defined by a pathological pattern of endothelial cell swelling and detachment from basement membrane, thrombi in the microcirculation and dissolution or attenuation of the mesangial matrix.

Pathophysiology of TMA in pregnancy is similar to that of pre-eclampsia where an imbalance of pro and anti-angiogenic factors resulting in endothelial dysfunction, inflammation and susceptibility to the development of microthrombi.

TMA in pregnancy is usually diagnosed based on clinical and pathological data, with a classic triad of:

1. Thrombocytopaenia
2. Haemolytic anaemia
3. Organ dysfunction
    a. CNS (altered conscious state)
    b. Acute kidney injury
    c. Cardiac dysfunction (evidence of myocardial ischaemia, sudden cardiac death)

Pregnancy and post-partum are high-risk periods for the development of TMA. Aside from the hypertensive disorders of pregnancy (pre-eclampsia, eclampsia, HELLP); pregnancy-associated TMA include thrombotic thrombocytopaenic purpura (TTP), atypical haemolytic uraemic syndrome (aHUS) and catastrophic antiphospholipid syndrome (CAPS).

Diagnosis [39]

Specific diagnostic criteria for pregnancy-associated TMA are:

- Thrombocytopaenia: platelets <100

- Anaemia: Haemoglobin <100 g/L
- Lactate dehydrogenase (LDH) >1.5 times upper limit of normal
- Undetectable haptoglobin
- Negative direct erythrocyte antiglobulin test

And

- Schistocytes on blood film (Fig. 88.4), or
- TMA features on renal biopsy (or biopsy of another organ)

Pregnancy-associated TMA presents a significant diagnostic challenge. For example, pre-eclampsia and HELLP may present with features of TMA and patients with other causes of TMA may present with hypertension and proteinuria. Expert multidisciplinary input from obstetricians, nephrologists, haematologists and intensivists is essential when caring for these patients. While awaiting a definitive diagnosis, priority for treating clinicians is to determine whether plasma exchange or immunological therapy is indicated to avoid potentially life-threatening complications.

Thrombotic Thrombocytopaenic Purpura [39]

TTP is a type of TMA with mainly neurological involvement. It is a very rare condition in pregnancy, occurring in 1:17,000 to 1:200,000 pregnancies.

Pathophysiology

TTP occurs due to a deficiency in ADAMTS13, a specific metalloproteinase that cleaves ultra-large multimers of von Willebrand factor (vWF). The deficiency may be acquired, with development of an inhibitory antibody directed against ADAMTS13 or congenital, with pregnancy being a recognised trigger of TTP in women with a genetic ADAMTS13 deficiency. Pregnancy-associated TTP is defined by plasma ADAMTS13 activity of <20% in a pregnant patient with clinical features of TMA. [39]

Clinical Features

End-organ involvement and severity of symptoms are variable. The CNS is most frequently affected. Symptoms include headache, confusion, focal neurological deficits, seizures, stroke and coma. Gastrointestinal symptoms are also common. These include nausea, vomiting, diarrhoea and abdominal pain. Renal failure may be present. Cardiac symptoms and troponin elevation may be present and confer a worse prognosis. [40] The classic pentad of fever, thrombocytopaenia, haemolytic anaemia, neurological and renal dysfunction is seen in a minority of cases.

Definitive diagnosis is made by confirming a deficiency of plasma ADAMTS 13 activity (<20%). Access to and the turnaround time of this investigation may be challenging in remote areas and resource-limited settings. If there is sufficient clinical suspicion, treatment should not be delayed while waiting for ADAMTS13 level. Antibodies to ADAMTS13 should also be tested. Scoring systems such as the PLASMIC and French scores, are validated to predict ADAMTS13 deficiency in the general population. They have not been evaluated in the setting of pregnancy. [39]

Management

The preferred treatment of pregnancy-associated TTP is plasma exchange with concurrent steroid therapy (pulsed intravenous methylprednisolone or equivalent oral regimen). Delivery of the fetus is recommended in patients who do not respond to plasma exchange or if there are signs of fetal compromise or another obstetric indication for delivery. Platelet transfusions should be avoided in patients with TTP due to concern about worsening platelet aggregation, thrombosis and neurological dysfunction. If platelet transfusion is necessary to facilitate essential medical procedures, then they should be given with plasma exchange. [39]

Prognosis

Patients with hereditary TTP have a higher risk of relapsing in subsequent pregnancies, [39] the risk of acquired TTP in pregnancy is unknown.

Atypical Haemolytic Uraemic Syndrome

Atypical haemolytic uraemic syndrome (aHUS) is a type of TMA with primarily renal involvement. It is an extremely rare disorder in pregnancy. The estimated incidence of aHUS in the general population is approximately 0.5 in 100,000 persons and only 16% of these cases occur in women of child-bearing age. [41-43] aHUS is also known as complement-mediated thrombotic microangiopathy (CM-TMA).

Pathophysiology

Pregnancy-associated aHUS is mediated by complement pathway dysregulation, causing endothelial cell damage and the development of microthrombi in small vessels. The renal vasculature is particularly susceptible. Complement dysregulation may be caused by inherited pathogenic variants of complement genes or development of autoantibodies directed against complement proteins such as complement factor H. [44]

Clinical Features

Classically renal failure is the predominant feature of aHUS together with thrombocytopaenia and microangiopathic haemolytic anaemia. There is no specific diagnostic test for aHUS thus it remains a diagnosis of exclusion. Interestingly, pregnancy-associated aHUS is the only form of TMA to occur most frequently (up to 75%) in the post-partum period, up to 3 months after delivery. [39]

Management

The monoclonal anti-C5 antibody eculizumab is the recommended therapy for pregnancy-associated aHUS. It is safe for the mother and fetus and appears to be more effective than plasma exchange in achieving haematological remission, reversing acute kidney injury and preventing progression to end-stage renal failure (ESRF). [45], [46]

Prognosis

The relapse rate of aHUS during a subsequent pregnancy or post-partum period is approximately 25%. [42] Pregnancy is not contraindicated but patients should be counselled about this significant risk and a shared decision-making model used when discussing the risks and benefits of subsequent pregnancies.

Catastrophic Antiphospholipid Syndrome

Antiphospholipid syndrome (APS) is an autoimmune syndrome characterised by arterial or venous thromboembolism and/or pregnancy-related morbidity with persistently positive and high titre antiphospholipid antibodies (aPL), including anticardiolipin antibody, anti-beta2 glycoprotein I antibody and lupus anticoagulant.

Catastrophic antiphospholipid syndrome (CAPS) is a life-threatening variant of APS. It is characterised by the rapid onset of fulminant multiple organ failure and the development of large vessel and microvascular thromboses. CAPS occurs in approximately 1% of patients with APS. In 50% of cases, CAPS is a patient's first presentation of APS. [39], [47], [48]

Pathophysiology

The mechanism by which widespread thromboses occur, as opposed to a single thrombosis, is not well elucidated. Differences in antigen specificity, antibody titres, immune cell, coagulation activation and complement activation are likely implicated. [49] Most patients who present with CAPS have an additional thrombotic risk factor, pregnancy being one of them.

Clinical Features

Any organ system may be affected by microvascular and macrovascular thromboses.

- Kidneys: renal failure, proteinuria, haematuria, hypertension

- Brain: ischaemic encephalopathy, confusions, seizures, focal neurological deficits
- Heart: myocardial infarction
- Lungs: pulmonary embolism, pulmonary infarction, alveolar haemorrhage, ARDS
- Skin: livedo reticularis, purpura, skin necrosis
- Uteroplacental dysfunction – fetal distress and fetal demise

Thrombocytopaenia, microangiopathic haemolytic anaemia and disseminated intravascular coagulation are non-specific findings that are often present in CAPS.

Management

Patients with suspected or confirmed CAPS should be aggressively treated with anticoagulation, steroids and plasma exchange or intravenous immunoglobulin. Rituximab and eculizumab are usually reserved for refractory disease. Temporary discontinuation of anticoagulation to facilitate procedures or delivery could be done but anticoagulation should be re-established as soon as practicable.

Prognosis

CAPS in pregnancy is likely to be associated with high rates of fetal death, premature delivery and neonatal morbidity. In the general population, the mortality of CAPS reaches 30% even with aggressive treatment,[50], [51] with no pregnancy-specific data available.

Obstetric emergencies

Loki Bjorn Johnk, Josephine Gwyneth Laurie and Nai An Lai

Introduction

Intensive care units (ICU) are often involved in the care of critically ill obstetric patients. The incidence of critical illness among obstetric patients requiring ICU care ranges from 0.7 to 13.5 per 1000 deliveries [1-4] and pregnant or post-partum patients account for 0.4% to 16% of ICU admissions. [2, 5] Intensivists and obstetricians may face challenges in the management of critically ill obstetric patients in terms of volume of practice and barriers in teamwork and service interface.

Internationally, maternal mortality ratios vary from 12 per 100,000 live births in high-income countries to 430 per 100,000 live births in low-income countries. [6] Leading causes of maternal mortality and morbidity include venous thromboembolic disease, haemorrhage, pre-eclampsia/eclampsia, cardiovascular disease, sepsis and amniotic fluid embolism. [7] In Australia, maternal mortality ratio is relatively low at 5.6 per 100,000 births between 2018 and 2020. [8]

Factors influencing ICU utilisation for obstetric patients include recognition of critical illness in obstetric patients, ICU bed availability, access to intensive care service and availability of alternative areas of care such as high dependency units (HDU). The most common obstetric indications for ICU admission are obstetric haemorrhage and hypertensive disorders of pregnancy, including pre-eclampsia and eclampsia. [2, 3]

Maternal outcomes in ICU are relatively favourable compared to other critically ill patient cohorts because obstetric patients are in general younger with fewer co-morbidities. [2,7,9] Due to physiological changes in pregnancy, ICU-specific scoring systems such as the acute physiology and chronic health evaluation (APACHE) I-IV score, simplified acute physiology score (SAPS) I-III and sequential organ dysfunction score (SOFA) may overestimate mortality in the obstetric cohort especially when the cause of ICU admission is obstetric in nature rather than general medical or surgical issues. [9-12]

High-risk and comorbid pregnancy is an intrinsically multi-faceted process requiring multi-disciplinary care. Antenatal guidelines repeatedly emphasise the importance of a multi-disciplinary approach to various obstetric co-morbidities and complications, including placenta accreta spectrum disorders, adult congenital heart disease and hypertensive disorders of pregnancy. [13-16] It follows that these, and similar conditions, should be managed by a multi-disciplinary team for the critically ill obstetric patient. These teams can include obstetric, obstetric medical, maternal fetal medical, critical care, emergency, anaesthetic, pre-hospital, nursing, midwifery, neonatology and all medical and surgical subspecialty teams. Communication between teams in this setting is paramount, with one review citing 31% of adverse obstetric events attributable to issues related to communication. [17] Management of obstetric emergencies should follow standard crisis resource management principles, with particular attention to structured handovers, closed-loop communication, graded assertiveness and local and hospital-wide situational awareness. [18] Additionally, while obstetric emergencies historically incorporate a single-leader model, emerging evidence supports the practice of naturally evolving shared leadership models. [19] With the emergence of critical care outreach and virtual critical care service delivery, there is increasing awareness of the need to approach obstetric emergencies with a high degree of fluidity and flexibility, ensuring that all involved teams are trained and prepared to offer high-quality care, regardless of physical location. [20,21] Simulation training in obstetric emergencies is essential as obstetric emergencies are diverse in nature but infrequent. However, access to basic health care and speciality services will continue to be major challenges for pregnant patients in resource-poor settings. [6]

Physiological changes in pregnancy and the general approach to resuscitating pregnant patients will be outlined in this chapter. Common obstetric emergencies including obstetric haemorrhage, venous thromboembolism, sepsis, trauma and burns and cardiorespiratory failure will also be discussed in this chapter while highlighting general principles of good ICU care for obstetric patients. Hypertensive disorders of pregnancy and related pathologies including pre-eclampsia, eclampsia, haemolysis, elevated liver enzymes and low platelets (HELLP) syndrome, acute fatty liver of pregnancy and pregnancy-associated thrombotic microangiopathies are covered in Chapter 88 .

Physiological Changes of Pregnancy

There are many physiological changes in pregnancy that must be considered by the treating intensivist. All organ systems are affected, with changes dependent on the stage of pregnancy (Table 89.1). Given significant individual variation, it is crucial to assess physiological variables relative to each patient's baseline, including the pre-conception baseline. Additionally, while these physiological changes remain important, grossly abnormal values are most likely pathological and are worth investigating. The time for post-partum return to pre-pregnancy levels is variable but is generally days to weeks following delivery. The consequences of these changes include:

- Different normal value ranges for investigations.
- Altered presentations of non-pregnancy-associated pathologies.
- The need for awareness of pregnancy-associated pathologies.
- Understanding of how procedures should be modified for the pregnant patient.
- Implications for how physiological parameters affect the fetus.

Table 89.1

⇔ - within 5% of pre-pregnancy values, ⇑ - 5%–10% variation from pre-pregnancy values, ⇑⇑ - 10-30% variation from pre-pregnancy values, ⇑⇑⇑ - >30% variation from pre-pregnancy values

* No/insufficient published data to inform practice.

The following will describe the organ system changes most clinically relevant to the critical care practitioner.

Cardiovascular System

The cardiovascular system undergoes both anatomical and physiological changes in pregnancy. The heart is displaced anterolaterally, leading to a left-axis deviation. The circulating blood volume increases by 40% to 50%, with a disproportionate increase in plasma volume over red cell volume, leading to dilutional anaemia. [22-24] The World Health Organisation (WHO) defines anaemia in pregnancy as Hb < 110 g/L during first and third trimesters, Hb < 105 g/L during the second trimester and Hb < 100 g/L post-partum. [25] This increase in circulating volume means standard haemodynamic markers of hypovolaemia may initially be masked.

Heart rate (HR) increases slightly from the first trimester (approximately 9 bpm from baseline) throughout the pregnancy. [26] There is concurrent mild 4-chamber cardiac chamber dilatation, frequently with right-sided predominance and left ventricular hypertrophy. [27] It has been reported that up to 17.9% of term pregnancies exhibit echocardiographic parameters that would be consistent with diastolic dysfunction.[28] While there is a slight decrease in blood pressure from baseline in the first trimester, both systolic and diastolic blood pressures subsequently rise throughout the remainder of the pregnancy. Systolic blood pressure increases 6 to 9 mmHg from its early pregnancy nadir to its maximum at term, while diastolic blood pressure increases 7 to 10 mm Hg.[26] Systolic blood pressure readings below 95 mmHg should be concerning if inconsistent with the patient's baseline.

Cardiac output (CO) increases significantly during pregnancy, due to a combination of decreased systemic vascular resistance, increased HR and, to a lesser extent, increased stroke volume. This increase in CO can be up to 30% to 40% during the course of pregnancy.[29-31]

Respiratory System

There are profound changes in respiratory physiology during pregnancy. Superior displacement of the diaphragm and changes in its dimensions decrease the functional residual capacity (FRC) by 20% to 30%,[32,33] while increased progesterone-induced sensitivity to CO_2 leads to an increase in tidal volumes (up to 50% from baseline) and thus minute ventilation. Total lung capacity (TLC) is maintained by changes in lateral and anteroposterior dimensions. Interestingly, despite near-universal reports of dyspnoea in pregnancy, respiratory rate exhibits little variation from pre-pregnancy levels, meaning tachypnoea remains a good marker of clinical deterioration.[34]

This resultant hyperventilation means that mild chronic respiratory alkalosis is a normal finding in pregnancy ($PaCO_2$ 27 to 34 mm Hg), with correspondingly lower normal bicarbonate levels (17 to 21 mmol/L).[35,36] These changes help facilitate adequate gas exchange across the placenta. The pregnant patient also has a significantly increased metabolic rate, which contributes to early oxygen desaturation with apnoea.

There is a mild decrease in PaO_2 and SaO_2, particularly with progression from second to third trimester. Nonetheless, SaO_2 levels of 93% or less should be considered abnormal.[26] Hospital maternal early warning systems frequently set higher targets (such as 94% or lower in the

Queensland maternity early warning maternity tool, Q-MEWT) to increase the sensitivity of the tool. [37]

Finally, in late pregnancy, there is decreased chest wall compliance due to increased abdominal size and breast enlargement, with the potential for increased ventilatory pressures.

Gastrointestinal System

With decreased lower oesophageal sphincter tone and gastric compression by the gravid uterus, oesophageal reflux is common in pregnancy. Gestational nausea is also common, up to the severity of hyperemesis gravidarum. These lead to significantly increased baseline aspiration risk, particularly during intubation. [38]

Haematological System

Pregnancy is a hypercoagulable state. Prothrombotic factors are upregulated to different degrees, with decreased levels or resistance to antithrombotic factors, such as protein S, activated protein C and antithrombin III. The result is significantly increased risk of all thrombotic pathologies and complications. Fibrinogen level is elevated throughout pregnancy with reduced fibrinolytic activity, marking a need for higher fibrinogen target during resuscitation than in the non-pregnant population. A mild leucocytosis is also normal in pregnancy, making white cell count a less reliable marker of infection. Platelet count generally remains within normal ranges during pregnancy. [39], [40]

Renal System

While all elements of the renin-angiotensin system are upregulated, pregnancy is an inherently angiotensin II resistant state, as evidenced by progesterone-induced decreases in vasomotor tone and decreased sensitivity of angiotensin 1 (AT_1) receptors. The kidneys experience a state of hyperfiltration, with greatly increased renal blood flow and glomerular filtration rate (GFR). This results in low levels of glucosuria and proteinuria. An increase in vasopressin secretion contributes to renal fluid retention.[41], [42]

The net effect on water/sodium regulation is a decrease in average osmolality to 270 mOsm/kg and mild hyponatraemia (average serum sodium of 135 mmol/L).[43]

Some degree of renal calyceal dilatation is normal in pregnancy, particularly on the right, due to ureteric compression by the uterus. These changes can predispose to urinary stasis and urinary tract infections.

Pharmacodynamics and Pharmacokinetics in pregnancy

The physiological changes of pregnancy have a large impact on pharmacodynamics and pharmacokinetics. Historically, dosing studies excluded pregnant patients, thus dosing guidelines in pregnancy often extrapolate from studies on the non-pregnant population. Pregnant patients have larger volumes of distribution, changes in hepatic metabolic enzymatic levels, augmented renal clearance, changes in gastrointestinal absorption and altered levels of protein binding.[44], [45] Additionally, choice of drug and dose will be influenced by the degree of placental transfer and the risk to the fetus. In the post-partum period, medications administered to the mother may be transmitted through breastfeeding.

Medications with significant efficacy or toxicity implications should be dosed with specialist obstetric and pharmacy input, using available online guidelines.[46-48]

Resuscitation in Pregnancy

Resuscitation of the pregnant patient requires consideration of important differences from the non-pregnant patient. The stratification of causes of cardiorespiratory arrest must include both pregnancy-associated and non-pregnancy-associated conditions. Pre-test probability for certain pathologies, such as pulmonary embolism should be higher than in the non-pregnant population. Pregnancy-specific causes of cardiac arrest include amniotic fluid embolism, hypertensive disorders and pregnancy-related sepsis or haemorrhage. Hospitals should have provisions in their cardiac arrest emergency alert system to ensure that obstetric, neonatal and critical care teams are present for maternal cardiac arrests.

Airway and Breathing

Intubation of the pregnant patient should be assumed to be difficult. Altered anatomy, airway oedema, increased aspiration risk, weight gain and a greater propensity to desaturate mean that intubation should be conducted by the most experienced available operator. [49] These changes mean that a pregnant patient may require a smaller endotracheal tube than the non-pregnant patients. Additionally, apnoea time should be minimised, and rapid desaturation anticipated. Cricoid pressure is no longer routinely recommended. [50-52] As always, intubation during a cardiac arrest should not significantly interrupt resuscitative compressions and ventilation. All induction agents and muscle relaxants can be used in pregnancy. [44]

Compressions and Defibrillation

High-quality cardiac compressions should commence as soon as cardiac arrest is confirmed. Positioning of hands on the chest and anterolateral placement of defibrillation pads should be the same as standard basic life support (BLS) and advanced life support (ALS). [53] Care should be taken to place the apical pad beneath breast tissue.

There are variable recommendations regarding left lateral tilt of the patient during cardiac compressions, given concerns about decreasing the efficacy of compressions. However, manual left uterine displacement, using either one or two-handed techniques, is recommended, to minimise aortocaval compression. [50-52] This likely becomes relevant at 20 weeks gestation or with a fundal height above the umbilicus. [54] The use of transthoracic echocardiography is becoming more common in maternal resuscitation. The Rapid ObStetric Screen Echocardiography (ROSE) scan has been developed to specifically account for anatomical and physiological changes in pregnancy. [55] It should only be performed by an experienced practitioner, with awareness that subcostal views are likely to be limited due to abdominal distension.

Perimortem Caesarean Section should be considered in the setting of maternal cardiac arrest. This should be performed by a dedicated team of practitioners, taking care to avoid harm to the patient. It should be commenced within four minutes of arrest without return of spontaneous circulation (ROSC), to maximise maternal-fetal outcome. [50-52]

Acute Respiratory Failure

Causes of acute respiratory failure in pregnancy are extensive. It has been reported to complicate 0.1%–0.2% of all pregnancies. [56] Pregnant patients are affected by all causes of acute respiratory failure seen in the non-pregnant population and are also more prone to acute pulmonary oedema, due to increased circulating volume, decreased oncotic pressure and increased capillary permeability. Additionally, obstetric conditions such as pre-eclampsia, placental abruption and obstetric sepsis can all precipitate acute respiratory distress syndrome (ARDS).

Asthma may be exacerbated in some women during pregnancy and should be treated using the same modalities and medications as in the non-pregnant population. While there is a theoretical risk of salbutamol worsening uterine atony following a post-partum haemorrhage, this should not preclude its use for management of significant asthma exacerbations.

Mechanical ventilation of obstetric patients should use standard ARDSNet open lung ventilation techniques. [57], [58] Permissive hypercapnoea may be tolerated by mother and fetus, but there is currently insufficient evidence to define the upper limit of safety for hypercarbia. Hyperventilation should be avoided, due to concerns about compromising uterine arterial flow and fetal oxygenation. Pregnant patients may require higher positive end expiratory pressure (PEEP) to prevent basal collapse. Ideal management of gas exchange is unknown, but recommendations exist to aim for normocapnoea and higher oxygenation targets than for the general population (SpO_2 ≥94–95%, PaO_2 >65–70 mm Hg). [59], [60] Non-invasive ventilation may avoid the risks of intubation, but should be used cautiously, given the increased aspiration risk. It should be reserved for patients who are awake, able to protect their own airway and whose cause of respiratory failure is likely to resolve quickly. It should never delay endotracheal intubation if indicated.

For centres with experience in proning patients, obstetric patients can be proned for refractory hypoxic respiratory failure, as long as care is taken to avoid abdominal and uterine compression. PaO_2/FIO_2 values are significantly improved by prone positioning and reports of adverse fetal outcomes are rare.[61, 62] Proning should be protocolised and practiced within each ICU, with the capability to perform frequent or continuous fetal monitoring via cardiotocography (CTG).

Pregnant individuals are at higher risk for hospitalisation and severity of disease from COVID-19.[63] COVID-19 is associated with pre-eclampsia, pre-term delivery and stillbirth. Pregnancy also places the patient at an even higher risk of thrombotic complications of COVID-19.[63, 64] COVID-19 vaccination is generally considered safe and effective in pregnancy.[65]

Recommendations for treatment of pregnant patients with COVID-19 include systemic corticosteroids for patients requiring oxygen. Patients considered for delivery and requiring steroids for fetal lung maturation should receive lung maturation doses initially, then transition to COVID-19 dosing. Most biologic agents are currently to be avoided, except tocilizumab, if evidence of systemic inflammation or remdesivir, if requiring oxygen, but not mechanical ventilation.[66] Standard delivery and mother/baby bonding moments are to be encouraged with use of routine hygiene procedures.

Extracorporeal membrane oxygenation in pregnancy

Veno-venous and veno-arterial extracorporeal membrane oxygenation (VV and VA-ECMO) have both been successfully used in pregnancy for various causes of respiratory and cardiac failures. Maternal and fetal outcomes have been acceptable, with 60%–80% maternal and fetal survival rates reported.[67] Use of obstetric ECMO has increased in the last decade, particularly during the COVID-19 pandemic. All pregnant patients should be considered as ECMO candidates, particularly patients with pulmonary embolism, amniotic fluid embolism, ARDS and peripartum cardiomyopathy.

There are several important considerations when approaching ECMO for the pregnant patient. While bicaval cannulation may be superior to meet the demands of a higher CO, there are concerns about uterine abdominal vessel compression compromising flow. If this is of significant concern, dual-lumen cannulation may be preferable.[68]

Anticoagulation with intravenous unfractionated heparin appears safe but precludes the use of neuraxial anaesthesia in the event of delivery and preparation must be made for significant post-partum haemorrhage in the event of delivery.

There is insufficient evidence to guide ECMO haemodynamic and ventilatory targets, beyond baseline values for the patient. The fetus should be treated as an important end-organ, with continuous monitoring via CTG.

Timing of delivery is dependent on gestational age, goals of care, fetal monitoring and maternal stability. This complex decision should be established by an experienced multi-disciplinary team.

Trauma in Obstetric Patients

In Australia, maternal deaths from motor vehicle accidents, homicide and suicide are rare.[8] However, trauma is the leading non-obstetric cause of maternal death and the most common cause of fetal demise internationally.[69]

International data indicates that injuries complicate between 6% and 8% of all pregnancies[70]; 0.4% require hospitalisation and 0.1% experienced major trauma.[69,71] Conversely, 1% to 1.5% of women of reproductive age admitted for traumatic injuries are pregnant thus a pregnancy test should be performed on all women of childbearing age who present with trauma unless they are obviously pregnant.[69,72]

Common causes of trauma in pregnancy include domestic violence (8307/100,000 live births), motor vehicle accidents (207/100,000 live births) and falls (49/100,000 live births).[73,74] Motor vehicle accidents are the most likely cause of major trauma that requires hospital admission.

Mechanistically most pregnant patients suffer blunt trauma with penetrating injuries affecting 1.5% of injured pregnant patients.[73]

Trauma in pregnancy is challenging because there are two patients to consider during resuscitation. Nevertheless, the best strategy to optimise maternal and fetal outcomes is to prioritise maternal resuscitation and not withhold necessary investigations or treatment because of pregnancy.[72] Collaboration between the trauma team, the obstetric team, the ICU team and the neonatal team is essential.

General principles of Advanced Trauma Life Support (ATLS) or the equivalent Early Management of Severe Trauma (EMST) apply to trauma in obstetric patients with some special considerations as listed as follows[72, 75-77]:

- Primary survey and resuscitation: All principles of primary survey in trauma are applicable when caring for pregnant patients with trauma. Special considerations when resuscitating pregnant patients have been outlined earlier in this chapter.
- If an intercostal catheter is indicated, insert 1 to 2 intercostal spaces higher than usual in the third or fourth intercostal spaces as diaphragm is elevated in late pregnancy. Be aware of the possibility of diaphragmatic rupture and herniation of abdominal contents into the pleural cavity.
- Avoid excessive crystalloids as low oncotic pressure in pregnancy predisposes pregnant patients to pulmonary oedema.
- Fetal assessment should be done after primary survey and resuscitation of the pregnant patient. fetal heart rate (FHR) monitoring in the form of cardiotocography (CTG) is indicated in pregnancy of more than 23 weeks gestation. CTG is highly sensitive in detecting fetal distress and maternal perfusion issues. CTG findings that may indicate uteroplacental insufficiency include decreased FHR variability and late decelerations.
- Damage control surgery should be considered a life-saving measure in consultation with the surgical, obstetrics and emergency teams.
- Secondary survey encompasses taking a focused history, conducting top-to-toe physical examination to identify maternal injuries and

relevant investigations including ultrasound, radiological imaging, point-of-care tests and laboratory tests.

- Focused history (**CODE**) encompasses **C** omplications of pregnancy, **O** bstetric history, **D** ating method and estimated due date, **E** vent details including bleeding, fluid leaking, contractions and fetal movement.
- Focused abdominal sonography in trauma (FAST) is indicated in haemodynamically unstable patients to identify presence of free fluids in the peritoneal and pleural cavities. It is accepted that FAST can be technically challenging in pregnant patients and subcostal view is limited in late pregnancy.
- In general, the risks to the fetus from radiological imaging are small compared with the risk of missed or delayed diagnosis of injuries in trauma.
- Obstetric haemorrhage in trauma is often underestimated and may be concealed. Differential diagnoses of vaginal bleeding in a pregnant trauma patient include placental praevia, vasa praevia, placental abruption, bloody show from cervical dilatation with pre-term labour and uterine rupture. Sterile speculum vaginal examination may be indicated.
- Do not perform digital vaginal examination until placenta praevia is excluded.
- Be aware of the high risk of significant retroperitoneal haemorrhage following pelvic injuries.
- Volume resuscitation with blood products is the preferred approach to manage haemorrhagic shock. Vasopressors may exacerbate uteroplacental insufficiency and should be used as adjunct to volume therapy.
- Fibrinogen replacement, tranexamic acid and the use of viscoelastic haemostatic assays to guide transfusion are recommended in accordance with the management of obstetric haemorrhage.
- Prevent rhesus D (Rh) alloimmunisation in women with Rh-negative blood group by transfusing O-negative blood when needed until cross-matched blood becomes available.
- All Rh-negative pregnant women with trauma should receive at least a standard dose of Rhesus immunoglobulins (300

micrograms) and the need for additional doses should be guided by the result of a Kleihauer-Betke test.

- Tetanus toxoid is not contraindicated in pregnancy and should be administered as part of wound management when indicated.

Burns

Burn injuries are uncommon in pregnancy with an estimated incidence of 0.17 cases per 100,000 live births. [72] On the other hand, 1% to 8% of female patients who present to hospitals with burns are pregnant. [78] Burn injuries are associated with significant maternal and fetal mortality and morbidity but there is paucity of high-quality evidence to guide practice. As such basic principles of burns management should be applied when managing pregnant patients with burns.

Airway and breathing assessment should include assessment and management of inhalational injury. Early and pre-emptive endotracheal intubation should be considered as inhalational injury is associated with adverse maternal and fetal outcomes. [78] Fetal distress could be an early sign of carbon monoxide or cyanide toxicity and these should be managed according to contemporary guidelines. [79], [80]

In the absence of evidence specific to the pregnant population, an assessment of total body surface area burned (TBSAB) should be done using the Wallace rule of nines or the Lund-Browder chart. Fluid resuscitation should be guided by the Parkland formula. TBSAB of 55% or more is associated with almost 100% maternal mortality and as such is an indication for emergent Caesarean section if the fetus is viable. [72]

Maternal Sepsis and Septic Shock

The WHO defines maternal sepsis as a life-threatening condition characterised by organ dysfunction resulting from infection during pregnancy, childbirth, post-abortion or post-partum period. [81] Criteria for diagnosing septic shock in the general population remains valid for the obstetric population; namely hypotension requiring vasopressor therapy despite adequate fluid resuscitation or serum lactate greater than 2 mmol/L despite adequate fluid resuscitation.[82,83] Global prevalence of maternal sepsis is 4.4% among live births, with incidence of 9 to 49 per 100,000 deliveries.[81] Sepsis is one of the most common direct causes of maternal mortality, accounting for 11% to 16% of maternal deaths worldwide and in Australia.[6,8,84]

Common sources of maternal sepsis include urinary tract infection (pyelonephritis in particular), chorioamnionitis, endometritis and pneumonia.[85] Bacterial pathogens are most commonly implicated with Group A beta-haemolytic *Streptococcus* , *Escherichia coli* and Group B Streptococcus the predominant pathogens.[82,85] Refer to Table 89.2 below for a list of pathogens commonly associated with maternal sepsis.

Table 89.2

Infectious causes of sepsis in pregnancy and post-partum [82]

Infection	Pathogens
Bacterial – common	Group A-beta-haemolytic *Streptococcus (GAS) pyogenes* *Escherichia coli* Group B *Streptococcus* *Klebsiella pneumoniae* *Staphylococcus aureus* *Streptococcus pneumonia* *Proteus mirabilus* Anaerobic organisms
Bacterial – less common	*Haemophilus influenza* *Listeria monocytogenes* *Clostridium species* *Mycobacterium tuberculosis*
Viral	Influenza Varicella zoster virus Herpes simplex virus Cytomegalovirus SARS-CoV2 (COVID-19)

Early recognition of maternal sepsis is paramount. Society of Obstetric Medicine Australia and New Zealand (SOMANZ) recommends using the obstetrically modified quick sequential organ failure assessment (omq-SOFA) score (Table 89.3) for screening and prompt identification of obstetric patients with sepsis and the obstetrically modified SOFA (om-SOFA) score (Table 89.4) for subsequent, more thorough, assessment. [82] Modifications were based on recognised maternal physiological changes in pregnancy and observations routinely recorded on maternity wards. In omq-SOFA, a lower systolic blood pressure cut-off of 90 mm Hg (instead of 100 mm Hg) and a higher respiratory rate cut-off of 25 breaths/min (instead of

22 breaths/min) are used. The Glasgow Coma Scale (GCS) is not routinely used in maternity practice and as such has been replaced with assessment of alertness. Creatinine cut-off values in omSOFA have been lowered in recognition of the physiological lowering of creatinine in pregnancy. A score of 2 or more on omq-SOFA identifies infected obstetric patients with high risk of poor outcomes and intensive care input should be sought. In the ICU setting, omSOFA could be used to confirm the diagnosis of maternal sepsis and to guide prognostication.[82,86] Other scoring systems that could be used to facilitate early recognition of maternal sepsis, including the modified early obstetric warning score (MEOWS) and the sepsis in obstetrics score (SOS).[84,87]

Table 89.3

Min , minute; *mm Hg* , millimetres of mercury; *qSOFA* , quick Sequential (sepsis-related) Organ Failure Assessment score.

Table 89.4

FIO_2 , fraction of inspired oxygen (expressed as a decimal); *MAP* , mean arterial pressure; *mm Hg* , millimetres of mercury; PaO_2 , partial pressure of oxygen (in mmHg); *SOFA* , Sequential (sepsis-related) Organ Failure Assessment score.

Effective multi-disciplinary management of maternal sepsis and septic shock encompasses the following principles as recommended by SOMANZ and in line with the WHO and the latest Surviving Sepsis Campaign (SSC) [82,85,88]:

- Early resuscitation – Ensure patent airway, supplemental oxygen as required, appropriate fluid resuscitation and tilting the pelvis to the left to reduce aorto-caval compression in hypotensive patients, monitor serum lactate, use dynamic rather than static haemodynamic variables to guide resuscitation and early consideration of vasopressor support in patients who are not fluid responsive and/or poorly tolerant of volume loading.

- Early administration of appropriate antimicrobials – Broad-spectrum antibiotics should be administered within the first hour after diagnosis of sepsis and ideally after the collection of blood cultures. Choice of antibiotics should be guided by likely site(s) of maternal infection, local susceptibility pattern and potential for teratogenesis. Antiviral should be considered if a viral aetiology is suspected or confirmed.
- Assessment of the fetus and timing of delivery – This should be guided by the obstetrics team and may involve ultrasonic assessment or CTG monitoring. Decision on the timing and mode of delivery is a complex process that involves consideration of the gestational of the pregnancy, fetal status, nature and severity of the maternal sepsis, response to resuscitation and the presence or absence of intra-uterine sepsis.
- Source control – Conditions such as chorioamnionitis, endometritis, pyelonephritis and appendicitis necessitate source control measures such as delivery of the fetus, removal of retained product of conception, insertion of ureteric stent and appendicectomy.
- Venous thromboembolism (VTE) prophylaxis – Both pregnancy and sepsis are independent risk factors for VTE. [89] Unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) are safe options in the absence of contraindications.

Major Obstetric Haemorrhage

Incidence and aetiology

Major obstetric haemorrhage remains an important cause of maternal morbidity with incidence ranging between 5% and 15% [90] and accounts for 6% of all maternal deaths in Australia. [8] Obstetric haemorrhage may be antepartum (defined as bleeding from the genital tract after 24 weeks of gestation), with common causes including placenta previa and placental abruption. [91] Delivery remains the definitive management of antepartum bleeding. Post-partum obstetric haemorrhage (PPH) is due to uterine atony in approximately 80% of cases, with abnormal placentation, retained tissues, trauma to the genital tract and coagulopathy accounting for most of the other causes. [92]

Management

The aims of management of PPH are summarised with the 5 Ts [90] :

1. Tone (uterine)
    a. Mechanical: Uterine massage or bimanual uterine compression (emptying the bladder may assist in this process).
    b. Pharmacological: The following agents may be given in combination.
        i. Oxytocin 5 units by slow intravenous injection (if already administered for 3rd stage management, a repeat dose may be given). Intravenous oxytocin infusion as per local protocol (e.g. 40 units of oxytocin in 500mL 0.9% sodium chloride over four hours)
        ii. Ergometrine 0.25 mg by slow intravenous or intramuscular injection, repeated if necessary 5 minutely up to a maximum of 1.0 mg; in the absence of contraindications and with caution regarding emetic effects.
        iii. Misoprostol (up to 1000 mcg) rectally. Prostaglandin and its analogues are the most potent of the uterotonics but also have the most serious adverse effect profile. Higher doses of misoprostol (800 microg or higher) have been associated with cardiovascular perturbations including profound hypotension, severe hypertension, cardiac arrhythmias and coronary vasospasm. [93] Bronchospasm and stoke have also been described.
2. Trauma of the genital tract: Also consider intra-abdominal sources such as ruptured uterus, broad ligament haematoma, subcapsular

liver rupture, ruptured spleen and ruptured splenic artery, hepatic artery or pancreatic artery aneurysm.

3. Tissue: retained products of conception with examination for and manual removal.
4. Thrombin (abnormalities of coagulation)
    a. Tranexamic Acid. Administration of 1g of tranexamic acid intravenously with a clinical diagnosis of PPH, repeat dose after 30 minutes if bleeding persistent. [94]
    b. Replacement of platelets and clotting factors utilising a massive transfusion protocol (MTP). Point-of-care testing has an increasing role in the assessment of PPH (e.g. TEG/ROTEM). Particular attention should be paid to the fibrinogen level with replacement (cryoprecipitate or fibrinogen concentrate if available) where the fibrinogen is <2 g.
5. Theatre: Surgical interventions should be considered early and include,
    a. Balloon tamponade.
    b. Haemostatic brace suturing (such as the B-Lynch suture).
    c. Bilateral ligation of uterine arteries.
    d. Bilateral ligation of internal iliac arteries by an experienced operator.
    e. Selective arterial embolisation if available.
    f. Hysterectomy.

Venous Thromboembolism

Incidence

The incidence of VTE ranges from 0.5 to 2 episodes per 1000 deliveries, which is a 5 to 10-fold increase in risk compared with non-pregnant women of comparable age. [95] Venous thromboembolism accounts for 11% of all maternal deaths and remains the leading direct cause of maternal death in Australia. [8] Risk factors for VTE in pregnancy include previous provoked and unprovoked VTE, thrombophilia, active autoimmune or inflammatory disorder, surgery, hospitalisation, severe hyperemesis or other causes of dehydration and medical co-morbidities (e.g. cancer, nephrotic syndrome, heart failure, sickle cell disease and diabetic nephropathy).[96] The use of VTE prophylaxis in the antenatal and post-partum periods should be guided by the VTE risk.[96,97]

Investigation

Accurate diagnosis of VTE in pregnancy is crucial but made challenging by the overlap of VTE symptoms with other important differential diagnoses and the normal physiological changes of pregnancy.[98] Use of a pregnancy-specific diagnostic tool may be helpful in determining the requirement for imaging, and the most appropriate modality, in consultation with the mother/parents. Appropriate imaging including chest X-ray, echocardiography, lower limb ultrasound, CT pulmonary angiography and/or ventilation-perfusion scanning should be utilised as indicated. The performance of D-Dimer in predicting VTE in pregnant patients remains controversial and baseline levels differ in this population.

Management

Low-molecular-weight heparin is the preferred treatment of VTE during pregnancy. Dosing is based on the early pregnancy weight or booking weight. Both once-a-day and twice-a-day dosing have been described.[95,99] Intravenous unfractionated heparin may be used if the patient is unstable or likely to require delivery imminently. Antepartum use of Vitamin K antagonists is relatively contraindicated and direct oral anticoagulants are contraindicated but may be considered in the post-natal period, with expert supervision.

Thrombolysis (systemic or directed) and thrombectomy (surgical or radiological) should be considered using the same indications as the non-pregnant population and recombinant tissue plasminogen activator has minimal placental transfer due it the molecule size. Additional caution is required for use of thrombolysis in the early post-partum period, as this can produce major obstetric haemorrhagic complications. This intervention should be reserved for life-saving purposes only in the early post-partum period. The use of ECMO as a rescue therapy in massive pulmonary embolism is well established and should be considered where available. [68] Inferior vena cava (IVC) filter placement may be indicated in the setting of acute VTE and imminent delivery when anticoagulation needs to be discontinued temporarily.

Whenever possible, delivery should be timed to allow appropriate cessation of anticoagulants. Mode of delivery should be obstetrically indicated and a multi-disciplinary team consisting of obstetricians, anaesthetists, physicians and midwives convened to define a care plan with the patient and their partner. Regional anaesthetic timing is well defined in many national and local protocols and re-initiation of anticoagulation should only occur after senior clinical review by an obstetrician and anaesthetist. An alternative care plan should also be considered in the event of unplanned pre-term delivery.

Amniotic Fluid Embolism

Incidence

Amniotic fluid embolism (AFE) is a rare condition characterised by the sudden onset of maternal cardiorespiratory compromise or collapse and haematological disturbance, which can rapidly lead to death. The incidence of AFE is reported as 5.4 cases per 100,000 patients giving birth in Australia and New Zealand, with a case fatality rate of 15%. Globally, mortality rates range between 20% and 60% and it remains a feature of maternal mortality statistics worldwide. [100]

Aetiology and clinical presentation

Contamination by amniotic fluid and fetal components into the maternal circulation creates intense pulmonary vasoconstriction and bronco-constriction. These effects may occur due to physical obstruction but also by the initiation of an intense inflammatory cytokine response to the fetal material. This inflammatory activation may precipitate coagulation and fibrinolytic pathways, creating a form of disseminated intravascular coagulation (DIC) syndrome.[101] The most commonly reported initial presenting features include premonitory symptoms (27%), hypotension (21%), shortness of breath (15%) and acute fetal compromise (15%).[100]

Diagnostic criteria

The American Society for Maternal-Fetal Medicine (SMFM) criteria for AFE are as follows[102]:

1. Sudden cardiopulmonary collapse or hypotension (systolic blood pressure less than 90 mm Hg) with hypoxaemia (SpO_2 less than 90%)
2. DIC, according to the International Society of Thrombosis and Haemostasis (ISTH) definition[103]
3. Symptomatology either during labour or during placental delivery (or up to 30 minutes later)
4. No fever

It is acknowledged that the diagnostic criteria are not comprehensive and diagnosis of AFE may be challenging. It remains a diagnosis of exclusion and a wide differential diagnostic list needs to be considered. This includes pulmonary embolism, peripartum cardiomyopathy, septic shock, myocardial infarction, venous air embolism, eclampsia, anaphylaxis and cephalad spread of spinal anaesthetic.

Management

Management is supportive following evacuation of the uterus and attendance to sources of bleeding. The requirement for hysterectomy to control bleeding is common. Invasive monitoring and echocardiography are useful to evaluate pulmonary hypertension and right heart failure as well as the effects of haemodynamic support.[104] The use of ECMO has been reported in the setting of refractory cardiogenic shock in this group.[68, 100]

Acute Pulmonary Oedema

Acute pulmonary oedema (APO) is seen in pregnancy and the post-partum in 0.08%–1.5% of deliveries. APO may occur in the setting of LV dysfunction or with preserved ejection fraction and may be cardiogenic or non-cardiogenic in origin. Aetiology is variable and includes undiagnosed cardiac disease, such as rheumatic heart disease valvulopathies, or more commonly, is associated with the hypertensive disorders of pregnancy such as pre-eclampsia, HELLP syndrome and eclampsia. [105] It is often precipitated by aggressive fluid replacement intrapartum. Usual APO management strategies apply.

Ovarian Hyperstimulation Syndrome [106]

Severe ovarian hyperstimulation syndrome (OHSS) pathogenesis involves increased capillary permeability resulting in leakage of fluid into extravascular spaces. This manifests as haemoconcentration, low albumin, ascites, pleural and rarely pericardial effusions. Severe fluid extravasation may also result in thrombosis, electrolyte disturbances, renal and hepatic abnormalities or ARDS. Impressive ovarian enlargement can result in ovarian torsion and would require surgical intervention. The management approach is otherwise supportive.

Peripartum cardiomyopathy [107]

Peripartum cardiomyopathy (PPCM) is characterised by a new onset of heart failure between the late third trimester of pregnancy and 6 months post-partum in previously healthy women, with no other cause of cardiomyopathy identified. Diagnosis requires echocardiographic evidence of left ventricular dysfunction (ejection fraction <45%) and usually shows features of dilated cardiomyopathy. The incidence varies from 1 in 1000 to 1 in 10,000 pregnancies and is significantly higher in Black African women. [108] PPCM often presents as acute heart failure and there is a strong association with the hypertensive disorders of pregnancy. The exact aetiology of PPCM remains controversial with possible causes including angiogenic imbalance (including prolactin and soluble Fms-like tyrosine kinase 1 (sFlt-1) pathways), genetic factors, inflammatory insults, viral triggers and autoimmune dysfunction.

Management is largely supportive of diuretics, inotropes and positive-pressure ventilation. Intra-aortic balloon pump, ventricular assist devices and ECMO may be used in severe cases, [68] with a view to transplantation. Bromocriptine therapy is used and considered safe, although data to support this strategy is based on animal studies or case reports. [107]

Chronic disease in pregnant patients

Advanced medical and surgical management has allowed women who were previously precluded from childbearing to consider pregnancy and motherhood. In addition to this new complex obstetric cohort, assisted fertility has enabled women of advanced maternal age to achieve pregnancy. Both aspects have altered the landscape of maternal morbidity and require highly skilled multi-disciplinary teams to help manage their pregnancy, delivery and post-natal course.

Women with pre-existing cardiac disease, for the most part, can achieve a safe and successful pregnancy. The caveat to this statement is women with cyanotic lesions, those with severe stenotic valve lesions and/or pulmonary hypertension, and women with significant aortopathies, who have a high fetal loss rate and significant maternal morbidity and mortality. Cardiac disease is currently the commonest indirect cause of maternal mortality. [8] The European Society of Cardiology pregnancy guidelines provide a concise and comprehensive summary of cardiac disease types and management strategies. [93] Further, the modified WHO guidelines (or alternatively scoring systems such as the ZAHARA) provide a table for stratifying cardiovascular risk for the treating team and allow for counselling of the patient and her family. [109] Pregnant women with significant cardiac disease should be managed in a specialised centre with experience with complex cardiac disease in pregnancy and access to interventional cardiology, cardiothoracic, cardiac anaesthetists and ECMO capabilities. Investigation and imaging modalities should be used as clinically indicated and consistent with non-pregnant patients. These include echocardiography, ECG, telemetry and stress testing.

Investigational/interventional procedures such as cardiac catheterisation and CT angiography should be utilised as clinically indicated with appropriate counselling regarding radiation exposure and provision of abdominal shielding as appropriate. Medication use in pregnancy should be guided by prescribers with experience and expertise in the field. Current pharmacological classification systems may not be helpful in defining actual pregnancy or lactation risks and may result in unnecessary avoidance of important treatments. [44] Anticoagulation management in pregnancy and across delivery is challenging and requires careful timing, utilising a specialist multi-disciplinary team. [93]

If required, cardiothoracic interventions (with cardiopulmonary bypass) during pregnancy are best timed in the second trimester but come with significant fetal loss. [93]

Other serious medical issues complicating pregnancy and highlighted by mortality data, include malignancy, serious neurological disease and complex autoimmune conditions. A commonality of risk and outcomes allows a systematised approach to these mothers regardless of the underlying condition. Disposition of the dyad in a specialist centre and the convening of a multi-disciplinary team, with familiarity with appropriate pharmacological, imaging and interventional management strategies are needed to successfully support these women.

Psychosocial elements of obstetric critical care

Pregnancy and the post-partum period are physically and psychologically vulnerable states. Critical illness and the usual functioning of the ICU can be distressing and isolating for mother and child. Management in the ICU runs the risk of neglecting standard peripartum care due to higher acuity management priorities. Additionally, many units do not have access to support services for the bereaved mother or family.

It is important for obstetric and critical care departments to work closely with one another to ensure whole-patient care of the mother-fetus dyad. Necessary management principles include:

- Fetal monitoring
- Ongoing standard antenatal care
- Lactation consulting and breast care
- Psychological supports, both during the pregnancy and post-partum
- Mechanisms for mother/child bonding time in the post-partum period, including virtual visits
- Appropriate monitoring of vaginal losses and perineal care
- Consideration and support of partners and family members
- Bereavement pathways that ensure privacy, compassion and respect

Acknowledgement

The authors would like to thank Professor Wendy Pollock and Dr Sarah Janssens for their advice and guidance in the preparation of this manuscript.

The critically ill child

Andrew J. Jones

The chapters on paediatric intensive care are intended to help intensivists outside specialist paediatric centres manage paediatric emergencies and to provide some context by describing how paediatric critical care services are organised. They should be read in conjunction with the relevant adult chapters, as there are many areas in common.

Cardiorespiratory Adaptation at Birth

At birth systemic vascular resistance rises rapidly as the large, low-resistance vascular bed of the placenta is disconnected from the newborn circulation. At the same time, the newborn takes its first breath, resulting in a fall in pulmonary vascular resistance and an increase in pulmonary blood flow and left atrial venous return. The consequent increase in left-sided pressures causes functional closure of the foramen ovale and ductus arteriosus. Blood, which previously short-circuited the right side of the foetal heart and the lungs via the foramen ovale, is forced into pulmonary circulation.

Although there is a sudden fall in pulmonary vascular resistance at birth, these changes are initially incomplete, with further reduction in pulmonary vascular resistance associated with regression in arteriolar muscularisation over the following days to weeks.

Under some circumstances, for example if the neonate becomes hypoxic, there can be failure to fully establish the normal postnatal circulation. Persistent pulmonary hypertension of the newborn (PPHN) is defined as the presence of right-to-left ductal and/or atrial shunting and elevated right ventricular pressure. Urgent measures to reverse hypoxaemia must be instituted to prevent further deterioration and death.

PPHN may be related to abnormalities of endogenous nitric oxide production and inhaled nitric oxide has proven a useful therapy.[1] Common causes of PPHN are meconium aspiration syndrome, sepsis (often due to Group B streptococcus), birth asphyxia and developmental lung disease, such as that caused by a congenital diaphragmatic hernia (CDH). Up to 20% of PPHN cases are idiopathic or primary, where in the absence of lung parenchymal disease elevated pulmonary arterial pressure is attributed to intra-uterine remodelling of the pulmonary vasculature.[2] A return to the foetal circulation may need to be medically or surgically induced in the case of ‘duct dependent’ congenital cardiac defects associated with either obstructive lesions on the right or left side of the heart, and as a temporising measure in transposition of the great arteries (TGA) to improve mixing of oxygenated and deoxygenated blood until normal circulation is surgically established. This may be partly achieved by an intravenous (IV) infusion of prostaglandin E_2 (a placental-derived vasodilating hormone) and/or re-opening of the foramen ovale by balloon atrial septostomy. Some intracardiac or vascular shunt lesions result in high pulmonary blood flow and increasing pulmonary pressure states. If left untreated, this elevated pulmonary vascular resistance may become fixed and will make subsequent surgical repair unfeasible.

Children Compared to adults

Treating a sick child necessitates knowledge of normal physiological parameters at the various stages of childhood. Parameter ranges can vary from source to source, and defining what is normal should be considered an evolving science.[3] As is the case in adult practice, interrogating the trajectory of physiological parameters over time can be as important as interpreting one-off values. Dosing medicines and sizing equipment are usually age and/or weight-based. There are numerous reference sources available, and there are likely to be local versions in each institution. There should be no barriers to ever looking up or checking a drug dose in paediatric practice.

The vulnerability of young children to environmental factors and to disease is important. They can be vulnerable due to their small size, immature anatomy and physiology, differing pharmacodynamics and reduced ability to communicate their needs, including the experience of pain. However, to view children only through the lens of vulnerability and the need for protection to obscure the nuances, overlook strengths and lose sight of them as individuals.[4,5] For example it is not always the case that children are more vulnerable to infectious diseases. Infants and young children are indeed susceptible to severe bacterial infections, but varicella zoster and SARS-CoV-2 infection, severe and potentially life-threatening in adults, are relatively benign in children; and infants in the first six months of life benefit from passive immunity derived from trans-placental passage of antibodies.

Growing children are in an advantageous position to heal and recover from illness. The osteogenic environment of the paediatric bone means fractures heal more quickly. Premature infants with significant bronchoalveolar dysplasia (‘chronic lung disease’) still have the potential to recover near-normal lung function by adulthood. The childhood brain undergoes continued maturation and development, as observed by the progressive attainment of milestones as myelination of motor and sensory nerves proceeds in a head-to-toe direction. Neural plasticity in childhood may allow for apparently remarkable recovery from brain injury.

This resilience should not, however, conceal the significant risk of post-critical care morbidity, and many children suffer a persistent worsening of their functional status after discharge from the paediatric intensive care unit (PICU).[6] There is a high prevalence of post-PICU psychological morbidity, including post-traumatic stress disorder (PTSD), affecting both the children and their parents.[7]

There are some key differences in anatomy and physiology that are noteworthy and can define the response to disease at various stages of childhood. Airways are narrow and therefore more prone to obstruction. This manifests clinically in conditions such as laryngotracheobronchitis (croup), and inflammation of the small airways in bronchiolitis. Target tidal volumes in relation to body weight remain constant regardless of age (5–7 mL/kg). The chest wall is more compliant than in adults which can lead to significant sternal and intercostal recession. Chest wall compliance also results in less negative intrathoracic pressure, meaning the lung volume at end-expiration is close to the lung volume at which small airway closure starts. Consequently, invasively ventilated children require PEEP, and applying CPAP during spontaneous ventilation can reduce the work of breathing. Early respiratory muscle fatigue can also be a problem in smaller children as muscles of respiration have fewer type 1 fibres.

Infants have a small, fixed stroke volume (1.5 mL/kg in a neonate), and so variation in cardiac output is mostly dependent on variation in heart rate. The ability to increase cardiac output at times of stress is thus relatively limited. An older child or adult can increase both stroke volume and approximately double the resting heart rate, but a neonate, with a resting heart rate of 150 bpm, cannot. A neonate may be able to achieve a heart rate, in sinus rhythm, of about 190 bpm. This is unlikely to be sustainable and will be at the expense of preload and ventricular filling. The fixed stroke volume can also blunt the response to fluid boluses in a younger child; from the age of about two years, the response to fluid becomes more like that of an adult. Despite the small stroke volume, the neonate has a cardiac index of 300 mL/min/kg. This decreases with age to 100 mL/min/kg in teenagers. Circulating blood volume at 70–80 mL/kg is higher than that of an adult. However, absolute blood volumes are small; what can appear to be a trivial amount of blood loss may lead to significant hypovolaemic shock. Infants in the intensive care unit often need blood transfusions due to blood loss from routine sampling for laboratory investigations.

The inexperience of the nascent immune system results in an increased susceptibility to some infections in the first six months of life. [8] The inflammatory response to infection, including the ability to mount a fever, may be lacking, and both cellular (chemotaxis and phagocytosis) and humoral (complement activity and opsonisation) immunity may be diminished. Cell-mediated immunity is significantly compromised in infants born without thymic function (DiGeorge syndrome); however, in the normal newborn, T-cell function is quite well developed. The B-cell system, responsible for antibody production, is immature at birth; however, to mitigate this risk, the neonate has passive immunity against some infections because of the placental transfer of maternal IgG. The protection conferred will depend on maternal immunity, but the infant's risk of disease can be significantly reduced when exposed to infections such as measles, mumps, rubella, tetanus, diphtheria, pertussis and influenza. In the breast milk-fed neonate, additional natural immunity is acquired because of immunoglobulin A, which protects against some acquired gastrointestinal infections.

Children have reduced energy reserves and higher metabolic demands compared to adults making them more vulnerable to starvation. Suboptimal nutrition in the PICU is associated with poorer outcomes. [9] Nutrition should be initiated as soon as possible after admission; and in the absence of contraindications (such as unresolved shock, or gut ischaemia), the preferred route of administration is enteral. If the enteral route cannot be used, and parenteral nutrition is being considered, there is evidence from a randomised controlled trial that there is benefit in waiting one week before starting. [10]

Recognition and resuscitation of the critically ill child

Lack of familiarity with normal physiological parameters in childhood can be a barrier to recognition of critical illness. For those unfamiliar or infrequently involved in the care of critically ill children, or even for those with more experience, it is essential to have a readily available information source of normal values for age. This information can be swiftly accessed online. [11]

Non-verbal and younger children are unable to fully communicate their symptoms. Generally, as children become more unwell, they will appear pale and lethargic, they will stop eating and they may vomit. These non-specific signs and symptoms may be the only clue in the history of, for example evolving sepsis or heart failure. Blood is directed away from non-essential vascular beds such as the skin, muscles and gut to maintain perfusion to essential organs. Careful observation of the child is essential, and it should be possible to form an instant impression of how sick a child is from the end of the bed.

It is usually reassuring if a child is crying loudly and/or vocalising normally. Stridor is a high-pitched noise on inspiration due to obstruction of the larynx or trachea. Stertor is a low-pitched snoring inspiratory noise usually due to pharyngeal obstruction and may be accompanied by the gurgling of secretions. It may be observed, for example in the child with cerebral palsy with impaired airway control and difficulty clearing secretions. Hypoxia in the context of airway obstruction and in the absence of lung parenchymal disease should be taken very seriously and may indicate that intubation is required imminently.

Tachypnoea may be accompanied by signs of increased work of breathing such as head bobbing, nasal flaring and sternal, intercostal and subcostal recession. Grunting respiration is an attempt by the child to generate PEEP by adducting the vocal cords and is usually a sign that respiratory support requires escalation. In bronchoconstriction, the volume (loudness) of the wheeze on auscultation does not necessarily indicate severity; more important is respiratory effort, conscious level and degree of tachycardia and tachypnoea. In the severest of bronchoconstriction, there may be no wheeze audible at all. The severity of wheeze is usually best assessed from the end of the bed.

Continuous pulse oximetry is essential in all critically unwell children, and an oxygen saturation of <92% in a child who is receiving oxygen is concerning. Children with weak muscles, such as in spinal muscular atrophy (SMA), may not exhibit the expected increased work of breathing in response to a respiratory infection. Tachypnoea and other respiratory signs may also be a sign of a circulatory or metabolic disease, for example sepsis or diabetic keto-acidosis (DKA).

When assessing the circulation, perfusion can be evaluated by feeling skin temperature and measuring capillary refill time (CRT). To assess central capillary refill time, press on the sternum for five seconds and colour should normally return in less than two seconds. This is not always reliable but is important when put together with other clinical signs. Persistent tachycardia should not be attributed to pain or agitation without a thorough assessment and a period of close observation. Hypotension is often a late sign requiring immediate treatment.

Assessing neurological status can be challenging. Pathological irritability or lethargy can be difficult to distinguish from normal childhood behaviours. However, any decrease in conscious level should be taken seriously, and is particularly worrying in the context of hypoxia or suspected brain hypoperfusion. Using the Alert, responsive to Pain, responsive to Voice, Unresponsive (AVPU) scale instead of a full Glasgow Coma Scale (GCS) is a pragmatic starting point when assessing and describing neurology. Pupillary responses also form an important part of the assessment.

Identifying the child with early sepsis can be a genuine challenge and the complexity of this should not be trivialised. Sepsis awareness campaigns are important but tend to neglect the nuances. Twenty percent of all children presenting to the emergency department have a febrile illness. [12] Fever reliably causes tachypnoea and tachycardia in children. As a consequence of this the paediatric systemic inflammatory response syndrome (SIRS) criteria are modified to include a mandatory requirement of abnormal leukocyte count. [13] Children with self-limiting viral infections can look surprisingly unwell when their temperature is high, and the threshold for giving antibiotics is therefore already low, with 30% of febrile children in the United Kingdom (UK) receiving antibiotics. There is no biomarker or diagnostic test that can distinguish the child with potentially life-threatening bacterial infection from the child with a benign viral infection. The importance of parental concerns is emphasised in some guidelines, although the utility of parental concern as a predictive factor for serious bacterial infection in children is not well supported by current evidence. [14] However, a parental sense that there is something worrying and different about *this* illness should be acknowledged and incorporated into the clinical assessment.

In the UK, congenital malformations are a major cause of death in infants and children. Structural abnormalities of major organs or systems, such as the heart, lung, brain and skeleton, may be diagnosed using antenatal ultrasound scanning and/or are usually obvious at birth. Some, however, may be unmasked later. In the wintertime cases of respiratory syncytial virus (RSV) surge and primary and secondary care facilities are inundated with bronchiolitic infants. Amongst this milieu of coughing and wheezing babies, there will be children with ventricular septal defects (VSDs) who due to RSV infection have been tipped into heart failure, or there is in fact no intercurrent infection at all, but the symptoms and signs of cardiogenic shock are masquerading as a pneumonia.

Some genetic problems may not become apparent until much later. The urea cycle disorder (UCD) ornithine transcarbamylase (OTC) deficiency, where reduced activity of the urea cycle enzyme OTC results in accumulation of toxic ammonia, often presents in the first week of life with encephalopathy and seizures. It has also been described as presenting for the first time in adolescents and young adults, for example following a dose of corticosteroids. [15]

All clinicians are vulnerable to anchoring bias, and it is as important in paediatrics as it is in other branches of medicine to remain open minded. The infant with a VSD and heart failure, if correctly identified, could be trialled on diuretics and nasal CPAP (CPAP may be helpful in treating pulmonary oedema and can increase intrathoracic pressure and augment stroke volume). This child will need transporting to a PICU with on-site paediatric cardiology and cardiothoracic surgery. The comatose young person with a late presentation of a UCD needs hyperammonaemia to be promptly identified followed by rapid transport to a PICU (or adult ICU) that can perform continuous renal replacement therapy (CRRT). If this diagnosis is missed, the outcome will be severe disability or death.

Stabilisation and transport of the critically ill child

Paediatric critical care has become increasingly centralised. In the UK there are over 200 general acute hospitals and about 30 public PICUs. In Australia and New Zealand, there are just 10 PICUs serving a population spread across a vast geographical area. Consequently, critically ill children often do not present to a hospital that can provide ongoing intensive care. Dedicated paediatric critical care transport (PCCT) services have evolved to move children safely and promptly from local hospitals to PICU. In 2021 there were 18,300 admissions to PICUs across the UK and Ireland, and 6000 of these admissions were via a PCCT team. [16] In 2019 there were

12,900 admissions of children to intensive care across Australia and New Zealand, and 2600 of these admissions were transported by a specialist intensive care team.[17]

Dedicated transport teams offer several advantages: they encourage the development of expertise within the team, they serve as a hub where referring hospitals can obtain advice and decision support, and they provide a bed-finding service which is able to triage and allocate patients to the most appropriate unit. Mortality, morbidity and the incidence of adverse events are decreased with the use of dedicated, specialised services.[18], [19] Quality indicators can be used to measure the performance of such services, for example the time to patient bedside, and the occurrence of adverse events, including cardiac arrest.[20] Having a skilled and confident transport team also improves the experience for the child and family.[21]

There are, however, some circumstances where the nature of the disease process makes the transport explicitly time critical, and the delay in waiting for a PCCT team to arrive tips the harm/benefit equation towards a local (non-specialist) team transport.[22] The paradigm of time-critical transport is the life-threatening neurosurgical emergency, where the preference for urgent non-specialist transport is supported by national guidance in the UK.[23] Other situations where specialist intervention, not available locally, may be lifesaving, and rapid transport is essential, include abdominal crisis with threatened gut perfusion requiring surgery, TGA with intact ventricular septum requiring balloon atrial septostomy, obstructed total anomalous pulmonary venous drainage (TAPVD) requiring surgery and hyperammonaemia requiring CRRT. In cases where a non-specialist team is utilised, it is important to use the most competent and skilled personnel available; ideally a team that includes a senior practitioner with advanced airway skills. Advice and remote telephonic assistance should be available from the PCCT team. A checklist for transport by a non-specialist team is helpful to ensure that all eventualities have been considered.[24]

For the relatively stable child awaiting the arrival of the PCCT team, the adult intensive care unit, with its technically skilled nursing and medical team, may be an appropriate and safe environment. It is essential that under these circumstances the adult team is appropriately supported by local paediatricians, and the PCCT team continue to provide advice whilst they are en route.

Resuscitation and stabilisation are commenced by the team in the local hospital and then handed over to the PCCT team. Resuscitation should be as complete as possible, considering the natural history and severity of the disease and the interventions that can be carried out in the non-specialist paediatric hospital, and airway and vascular access contingency plans made to deal with any potential deterioration during the transport itself. Invasively ventilated children should have the appropriately sized cuffed endotracheal tube confirmed in an optimal position (usually in the middle of the trachea, seen at T2–T3 on the chest radiograph), a gastric tube to decompress the stomach, and the adequacy of ventilation monitored with continuous pulse oximetry and end-tidal carbon dioxide monitoring. All necessary equipment for re-intubation, in the case of accidental extubation, should be kept close at hand.

Children who have required volume resuscitation and are on vasopressors, or those where continued haemodynamic instability is anticipated, should have sufficient vascular access to allow ongoing fluid resuscitation and commencement or escalation of vasoactive drugs during transport. Adequate cardiovascular monitoring, in the form of continuous electrocardiographic trace and regular intermittent non-invasive or continuous invasive arterial blood pressure monitoring, should be in place.

Arterial access in children is warranted in those who are haemodynamically unstable and/or on vasopressors; those who need targeted blood pressure management (e.g. for cerebral perfusion pressure); and those who require frequent blood gas or electrolyte monitoring. Peripheral arteries, including radial, dorsalis pedis and posterior tibialis are preferable. Arterial access attempts must avoid the brachial artery as thrombosis may lead to limb loss.

Vascular access can be extremely challenging in children, and familiarity with intraosseous (IO) needle insertion is important. IO access provides ‘central’ access to a non-collapsible venous system into which almost all resuscitation drugs can be administered. As an approximate rule, in decompensated shock IO access should be attempted if IV access has not been established after 90 seconds. The limb accessed with an IO needle must be carefully monitored. [25] The placement of central venous lines (femoral, jugular and subclavian) in children is technically more difficult than in adults because of the small size of the vessels, and for the jugular approach, the short neck. Femoral central venous access is usually preferable to jugular access in children who have a coagulopathy, or if there is any suggestion of raised intracranial pressure. Ultrasound-guided central line insertion is now considered a standard of care. [26] Complications, including line-related infections, occur in children as they do in adults, and the risks can be reduced by adherence to a care bundle. [27] The need for prolonged venous access may warrant regular line changes or surgical or interventional radiological implantation of a central venous device.

In children with shock, it is often preferable to commence vasopressors early in the resuscitation process, and usually in advance of attempts at central venous access. International guidance on resuscitation of septic shock in children suggests fluid refractory shock should be identified and a vasopressor commenced at fifteen minutes, following 40–60 mL/kg of fluid resuscitation. [28] It is safe to administer vasopressors, usually adrenaline and/or noradrenaline, via a peripheral venous cannula. [29] The infusion site should be carefully monitored, and this route of administration should not be considered a long-term solution if there is continued need for vasopressors in the PICU. However, for the 4–6 hours of resuscitation and transport, using a peripheral venous cannula provides a pragmatic solution where shock requires rapid reversal.

Organisation of paediatric intensive care

Paediatric intensive care developed in an uneven fashion across the developed world from the 1960s. In the 1990s countries such as the UK, Australia and New Zealand began to organise and centralise their paediatric intensive care services. There are benefits to having larger, regional units; the high volume means that the units develop a broad experience of complex and uncommon cases, a staff of specialist nurses and doctors are maintained, and staff training can take place in an efficient and organised manner. This has led to better outcomes for children requiring intensive care. [30] It is estimated that up to 450 children died annually in the UK during the 1990s due to lack of centralisation of PICU services. [31]

To monitor activity and outcomes, identify best practices, facilitate healthcare planning and study the epidemiology of critical illness in children, it is important to maintain secure and high-quality clinical databases of intensive care admissions. The Australia and New Zealand Paediatric Intensive Care Registry (ANZPICR) has been active since 1997. [17] In the UK and Ireland, the 33 paediatric critical care units and 14 PCCT teams report data to the Paediatric Intensive Care Audit Network (PICAnet), [16] established in 2002 by the Universities of Leeds, Leicester and Sheffield.

The 18,300 PIC admissions in the UK and Ireland in 2021 equated to 69,500 bed days. Just over two in five children admitted to a PICU are aged one or under, and two-thirds of admissions are aged five or under. Mortality has reduced steadily over the past decade; from 5.5% in 2003/2004 to 3.3% in 2021.

Scoring systems and quality metrics in PIC

Scoring systems in paediatric intensive care are used to describe severity of illness based on physiological variables, for example the Paediatric Logistic Organ Dysfunction (PELOD) score; [32] or the risk of death based on a combination of physiological variables and underlying disease, for example the paediatric index of mortality (PIM) score [33] or paediatric risk of mortality (PRISM) score. [34] For patients undergoing congenital cardiac surgery, scores based on the underlying diagnosis have been developed, such as the risk adjustment for congenital heart surgery (RACHS) score. [35] Scores enable analysis and comparison of performance with time, and across centres.

The reporting of key demographic and clinical information to PICANet or ANZPICR allows calculation of a standardised mortality ratio (SMR), the ratio of observed deaths to predicted deaths for each unit, which then enables comparisons to be made. The number of predicted deaths is calculated using the PIM3 score. [33] The participating units also report a selection of metrics to enable monitoring of the quality of care provided.

These metrics include staffing levels, emergency readmissions, unplanned extubations and transport team mobilisation time. Data visualisation can be used to compare the performance of individual PICUs. Funnel plots of SMR, with confidence limits to allow for natural variation, enable units which lie outside the confidence limits to be identified. This can trigger an investigation to understand any potential causes and aid learning.

PIC quality standards

There are suggested quality standards for a PICU published by the Paediatric Critical Care Society (PCCS) in the UK. [36] The document is detailed, but some key standards are listed here:

- A consultant (specialist) trained in paediatric intensive care should be able to attend the hospital within 30 minutes and should be available 24/7.
- There should be a comprehensive range of paediatric sub-specialty support, available 24/7.
- Junior medical staff with advanced life support skills including advanced airway and vascular access competence should be immediately available.
- There should be nursing staff with experience in paediatric intensive care, and a nurse: patient ratio to facilitate the appropriate level of care for each patient.
- There should be ready access to allied health professionals with specific training in paediatrics, including physiotherapists, dieticians, pharmacists, speech and language therapists, occupational therapists and child psychologists.
- 24-hour laboratory, radiological and pharmacy services should be available.
- The PICU should be purpose-built, recognising the special physical and emotional needs of critically ill children of different ages and their families.
- There should be an ongoing programme of teaching, education, research and quality assurance involving all members of the PIC multidisciplinary team.

- There should be support services and facilities for parents and families.

Changing patterns in the PICU

Whilst mortality has decreased in PICU over the past three decades, the proportion of survivors with moderate to severe disability has increased.[37] Children with life-limiting conditions make up nearly 60% of admissions to UK PICUs, and these children are more likely to die in the PICU than those without co-morbidities.[16, 38] The length of stay of children who die in the PICU has increased,[39] and a picture of early death due to treatment failure has been replaced by death following withdrawal or withholding of life-sustaining treatment after weeks of intensive care support.

PICU survivors may be technology-dependent. The number of children who receive long-term ventilation in the UK has risen rapidly in recent years,[40] in part due to the emergence of disease-modifying drugs altering the natural history of neuromuscular diseases, for example Nusinersen for SMA,[41] but also due to changing parental expectations. These changes are taking place against a backdrop of high-profile cases where the courts have been called upon to settle differences in opinion between parents and medical staff regarding the appropriateness of continuing intensive care.[42]

The future of PIC and whether it is sustainable in its current form will be influenced not only by technological and organisational developments, but also by the views of society with regard to resource allocation, parental autonomy and end-of-life care.

Upper airway obstruction in children

Paul James and Michelle Alisio

Upper airway obstruction is a particular clinical challenge in the paediatric population. The physics of airflow, the relative narrowness of the paediatric airway combined with the high rate of oxygen consumption in children can produce rapid and unexpected deterioration in their condition. Moreover, severe airway obstruction occurs infrequently in non-specialist centres and will require immediate intervention to secure a safe airway and maintain oxygenation. Successful management relies on an understanding of the paediatric airway, knowledge of the symptoms and signs that suggest unusual diagnoses or life-threatening obstruction, a realisation of what can and cannot be diagnosed without endoscopy and meticulous attention to basic anaesthetic principles.

Anatomical and Developmental Considerations

The upper airway technically extends from the nares to the junction of the larynx with the trachea. It includes the nose, the paranasal sinuses, the pharynx and the larynx. It changes in size, shape and position from the neonatal period through infancy and childhood to resemble the adult airway by the age of 8 years. [1]

Children have a proportionally larger head and occiput relative to body size. The large head forces the neck into flexion when supine, which is a potential cause of airway obstruction.

Nose

The nose is made up of nasal bones, the nasal part of the frontal bones and frontal processes of the maxillae. The septum divides the cavity into two with the exterior opening at the nares and the opening into the nasopharynx at the choanae.

If the membrane that separates the palatal processes during development does not rupture the neonate will have choanal atresia and will present with airway obstruction.

Infants are obligate nasal breathers, and secretions, oedema and blood easily block the small nasal apertures. Similarly, cellulitis, oedema or abscess formation in the paranasal sinuses will lead to airway obstruction.

Pharynx

The pharynx forms the common upper pathway of the respiratory and alimentary tracts. It is divided into three regions: the nasopharynx, oropharynx and laryngopharynx, which open into the nasal cavity, mouth and larynx, respectively.

The pharyngeal isthmus separates the nasopharynx and oropharynx. It closes off during swallowing.

The adenoids lie on the roof and posterior wall of the nasopharynx. These atrophy with age, but enlargement in early childhood may obstruct breathing. They may also be dislodged during instrumentation of the nose.

The oropharynx extends from the soft palate to the tip of the epiglottis. It is attached anteriorly to the base of the tongue via the glossoepiglottic folds, between which lies the valleculae.

At the entrance to the oropharynx is a collection of lymphoid tissue known as Waldeyer’s ring. This consists of the lingual tonsil at the base of the tongue and bilateral palatine tonsils as well as the adenoids and tubal tonsils. Inflammation, infection or invasion of this tissue may obstruct breathing. The shape and dimension of the oropharynx affect airway function, particularly during sleep.

The relatively large tongue decreases the size of the oral cavity and more easily obstructs the airway. Decreased muscle tone also contributes to passive obstruction of the airway by the tongue. The laryngopharynx extends from the tip of the epiglottis to the lower border of the cricoid cartilage. The larynx bulges back into the centre of the laryngopharynx leaving a recess on either side, known as the piriform fossa. This is a common site for the impaction of swallowed foreign bodies.

Larynx

The larynx is situated between the pharynx and trachea, extending from the base of the tongue to the cricoid cartilage.

The larynx consists of the thyroid cartilage, the cricoid cartilage, the paired arytenoids and the epiglottis, together with the small corniculate and cuneiform cartilages.

The laryngotracheal tube forms from the ventral wall of the foregut. The primitive glottis is formed at 10 weeks' gestation when the true vocal cords split. Failure of this process results in a congenital laryngeal web or atresia of the larynx. Incomplete division of the embryonic foregut results in a tracheoesophageal fistula.

The cricoid cartilage is shaped like a signet ring with the widest portion lying posterior. This is the only complete cartilage ring in the respiratory tract and is the narrowest portion of the larynx. Any oedema, infection or inflammation at this level results in airway compromise. Acquired subglottic stenosis as a result of prolonged or repeated tracheal intubation also occurs at this level. The larynx lies more anteriorly and higher, being at the level of the fourth cervical vertebra at birth, the fifth cervical vertebra at 6 years and the sixth cervical vertebra in the adult.

The epiglottis is a leaf-shaped structure attached to the posterior border of the thyroid cartilage by the thyroepiglottic ligament. The infant epiglottis is narrower, softer and more horizontally positioned than in the adult.

The superior location of the larynx in children may create difficulty in visualising the laryngeal structures because of the acute angulation between the base of the tongue and the laryngeal opening.

The vocal cords are innervated by the recurrent laryngeal nerve, which, if damaged, results in paralysis of the corresponding vocal cord, causing it to lie motionless in the midline and at a lower level than the opposite side. Bilateral paralysis results in complete loss of voice and the two vocal cords may then flap together causing a valve-like obstruction during inspiration.

The highly compliant and poorly developed cartilage leads to increased susceptibility to dynamic airway collapse in the presence of obstruction. Loss of muscle tone in the pharynx leads to airway obstruction at the level of the soft palate and epiglottis. Laryngomalacia is a congenital abnormality of the larynx and results from the laryngeal structure being more pliable and less rigid than in the adult. [2]

Pathophysiology

Resistance to laminar airflow increases in inverse proportion to the fourth power of the radius (Poiseuille's law) resulting in a marked increase in resistance to airflow with airway narrowing. The perpendicular cartilaginous ribs, which reduce the effect of the 'bucket handle' movement of the rib cage, and the immature intercostal muscles result in a mechanical 'disadvantage,' and children are more reliant on the diaphragm for inspiration. Signs of increased respiratory effort to overcome airway obstruction include head bobbing (use of neck muscles), subcostal and sternal recession, tracheal tug and forced expiration (abdominal muscle contraction in expiration). Chronic airway obstruction may lead to chest wall deformity.

A higher metabolic rate and oxygen consumption, together with a smaller functional residual capacity and fewer fatigue-resistant fibres in the diaphragm, means there is a little respiratory reserve and children with airway compromise can deteriorate very quickly.

However, children with chronic obstruction may manage surprisingly well with 'tolerable' airway noises and increased levels of respiratory work. Acute changes in airway calibre in these children may cause precipitous deterioration with accompanying hypoxia.

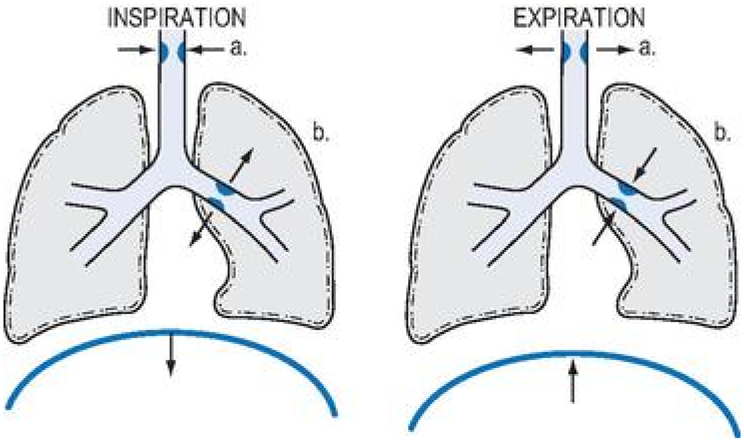
Clinical Presentation

Stridor is a harsh, vibratory sound produced by turbulent airflow and is the cardinal feature of upper airway obstruction. Symptoms and signs vary with the level of obstruction, the aetiology and the age of the child.

When faced with a child with possible airway obstruction the clinician must decide whether investigation and intervention are necessary and, if so, in what time scale. Very few diagnoses are truly clinical as it is only on direct endoscopy that the true cause of the problem can be confirmed. However, a careful history and examination are key to the decision-making process. Features that suggest obstruction needing urgent evaluation include episodes of colour change (pallor, cyanosis), apnoea, biphasic stridor, stridor when asleep and stridor from birth.

Extrathoracic obstruction is more pronounced during inspiration as the negative intraluminal pressure causes further airway narrowing. Obstruction is characterised by stridor and the prolongation of inspiration. Intrathoracic airway diameter increases on inspiration and signs and symptoms occur mainly on expiration. There is prolonged expiration, wheeze and air trapping as seen in asthma, which is a common misdiagnosis.

Biphasic stridor is characteristic of mid-tracheal lesions or impending complete obstruction at any level (Fig. 91.1).



The two-part labelled diagram shows the mechanics of breathing during inspiration and expiration. The left panel is labelled Inspiration and shows air entering the trachea, represented by arrows pointing inward as label a. The diaphragm, represented as a curved line, is moving downward. The lungs appear expanded, with outlines showing increased lung volume. Arrows inside the lungs show airflow into both lungs. The right panel is labelled Expiration and shows air leaving the trachea with arrows pointing outward from label a. The diaphragm is elevated compared to the inspiration panel. The lungs appear reduced in size, and arrows inside show airflow exiting the lungs. Label b is placed beside each lung, and dots mark the location in the tracheobronchial region. The overall diagram visually compares the changes in diaphragm position, lung volume, and airflow direction during breathing phases.

FIG. 91.1 Dynamics of (a) extrathoracic and (b) intrathoracic airways obstruction.

Aetiology

The aetiology may be classified in several ways including according to the site of obstruction (i.e. nose, pharynx or larynx), whether it is congenital or acquired, or whether it is due to infection, malignancy, trauma, etc.

Boxes 91.1 and 91.2 list the more common causes according to the age of the child.

Box 91.1

Common causes of upper airway obstruction in neonates/infants

Nose

- Choanal atresia

Oral cavity

- Encroachment of tongue on airway
- Macroglossia: Beckwith–Wiedeman, hypothyroidism
- Micrognathia: Pierre–Robin syndrome
- Haemangioma or venous/lymphatic malformation of tongue

Laryngeal abnormalities

- Laryngeal atresia
- Laryngomalacia
- Vocal cord paralysis
- Laryngeal cleft

Subglottic abnormalities

- Subglottic stenosis – congenital or acquired
- Subglottic haemangioma

Extrinsic lesions

- Mediastinal masses
- Cystic hygroma
- Foregut malformations
- Vascular abnormalities including rings and slings

Box 91.2

Common causes of upper airway obstruction in children

Oral cavity

Encroachment of tongue on airway

- Macroglossia: Beckwith–Wiedeman, hypothyroidism
- Micrognathia: Pierre–Robin syndrome
- Haemangioma or venous/lymphatic malformation of tongue

Other oral mass lesions

- Ectopic–lingual thyroid/thyroglossal duct cyst/dermoid cyst/ranula

Nasopharynx/oropharynx/retropharyngeal space

- Adenoid/tonsillar inflammation and abscess
- Lymphatic malformation
- Supraglottitis
- Foreign bodies
- Trauma/burns
- Neoplasms

Larynx/cervical trachea

Supraglottic

- Laryngomalacia
- Epiglottitis

Glottic abnormalities

- Vocal cord paralysis
- Laryngeal cleft
- Recurrent respiratory papillomatosis

Subglottic abnormalities

- Croup
- Subglottic stenosis
- Congenital
- Acquired (prolonged or traumatic intubation)
- Subglottic haemangioma

Infections of the Upper Airway

Viral and bacterial infections causing upper airway obstruction present in a very similar way and are often concurrent. A logical and useful approach to diagnosis is to identify the site of infection and consider the nature of the condition. [3]

Pharyngeal Infections

In the pharynx the site of infection is the peritonsillar bed in 49% of cases, the retropharyngeal space in 22% of cases and the parapharyngeal spaces resulting in abscess formation in 2%. [4]

Bacterial tonsillitis and peritonsillar abscess (quinsy)

Tonsillitis is caused by the aerobes *Streptococcus pyogenes, Streptococcus pnemoniae* and *Staphylococcus aureus* and the anaerobes *Fusobacterium* spp., *Prevotella* spp., *Porphyromonas* spp. and *Actinomyces* spp. Aerobes predominate in the acute primary infection, whereas anaerobes are associated with abscess formation or extension across tissues. Treatment is with third-generation cephalosporins or co-amoxiclav as there is a high incidence of penicillin resistance. [5] Metronidazole or carbapenems should be added if there is extension or abscess formation. Clindamycin or linezolid should be added to reduce bacterial exotoxin release if toxic shock is suspected.

Surgical removal in the acute setting is controversial as there is potentially an increased risk of bleeding, but if there is pus then drainage is indicated to prevent spontaneous rupture. [6]

Infectious mononucleosis (glandular fever)

Infectious mononucleosis is caused by the Epstein–Barr virus, which is a virus transmitted in saliva. Airway obstruction can occur and, despite steroids, 40%–88% of patients with airway obstruction require tonsillectomy. [7] The use of steroids does reduce the duration of fever, pharyngitis and abnormal haematological findings. [8]

Retro- and parapharyngeal abscess

Retropharyngeal abscesses are more common in boys (ratio 2:1) and occur at a median age of 3 years. The incidence appears to be rising. [9] The principal symptoms are fever, sore throat, trismus, torticollis, neck swelling and pain. Airway obstruction is rare.

Staphylococci and streptococci are the usual causal agents, but growth is often polymicrobial and treatment is with broad-spectrum antibiotics. Surgical drainage is indicated if there are symptoms persisting for 2 days or more, prior administration of antibiotics and fluid on computed tomography scan with a cross-sectional area of greater than 2 cm^2 . Complications include mediastinitis and Lemierre syndrome. [10]

Lemierre syndrome

Lemierre syndrome occurs when a pharyngeal/tonsillar infection is complicated by thrombophlebitis and septic emboli. The organism is usually *Fusobacterium necrophorum* . Local effects classically include thrombosis in the ipsilateral internal jugular vein and more distant spread with suppuration most commonly affecting the lungs, but also causing septic arthritis, osteomyelitis, meningitis and liver, renal and skin abscesses.

Ludwig angina

Ludwig angina is a diffuse infection of the submandibular and sublingual spaces. Severe pain, fever, malaise and dysphagia occur with swelling that can be large enough to cause airway compromise. Antibiotic choice is for tonsillar abscess, and surgical drainage is indicated if there is pus formation.

Larynx/Tracheal Infections

Croup

Croup (laryngotracheobronchitis) is common and usually caused by the virus parainfluenza, influenza type A or B, respiratory syncytial virus or rhinovirus. It is the commonest cause of acquired acute stridor in children and is a clinical diagnosis. There is a sudden onset of a seal-like barking cough usually accompanied by stridor, hoarse voice and respiratory distress. Symptoms are usually worse at night. It commonly affects children aged 6 months to 3 years with a peak incidence at 2 years. Only 2% of cases are admitted to hospital each year, of which only 0.5%–1.5% will require intubation.[11]

A Cochrane review investigated the use and effectiveness of steroids in the treatment of children with croup and recommended all children should receive either dexamethasone 0.15 mg/kg or prednisolone 1–2 mg/kg orally.[12] There appears to be no clinically significant difference between the two steroids regarding the need for further treatment or length of stay. Dexamethasone was associated with a reduction in re-attendances, which may be due to the shorter half-life of prednisolone.[13]

Nebulised epinephrine (adrenaline) 1/1000, 0.5 mL/kg to a maximum of 5 mL may be used to reduce airway swelling acutely in severe croup. This is a short-term measure and may allow time for the steroids to work or for experienced personnel to be called to the child. It may be repeated, if necessary, after 30–60 minutes, but further doses should be used with caution as repeated need suggests an extremely narrow airway.

If intubation is indicated, visualisation of the larynx should not be a problem; however, a smaller tracheal tube than normal for the age is usually required because of subglottic oedema. Once the obstruction is bypassed, most children can be managed on a Swedish nose with minimal sedation and arm splinting. Extubation may be attempted after 72 hours (or earlier if a large leak develops). Around 10% will require re-intubation.

Epiglottitis

Very few clinicians have seen epiglottitis since the introduction of *Haemophilus influenzae* type B vaccination in 1992. In children, it is still almost always due to infection with *H. influenzae* type b (Hib), although it can be caused by beta-haemolytic streptococci, staphylococci or pneumococci. In a retrospective study, 10% of children presenting with epiglottitis were found to have Hib infection, despite having been vaccinated. [14]

It occurs usually in children aged 2–6 years, with a peak incidence at 3 years.

Epiglottitis is painful. The most common signs are rapid onset of high fever, sore throat, inability to control secretions, classic tripod positioning, difficulty breathing and irritability. Adults may have a more indolent presentation and may not require airway intervention (only about 11% of adults require intubation whereas most children do). No action should be taken that could stimulate a child with suspected epiglottitis, including examination of the oral cavity, starting intravenous lines, blood or even separation from a parent for x-rays or ultrasound. Similar caution is required in fulminant acute epiglottitis in adults. A lateral neck radiograph will show a markedly enlarged epiglottis, referred to as a ‘thumbprint sign’. If the airway is not at risk, then ultrasonography is useful for the prompt diagnosis of acute epiglottitis and monitoring treatment outcomes. In the midsagittal view, the hyoid bone and swollen epiglottis form a P-shape.

The key to management is to secure the airway under inhalation anaesthesia with an ear, nose and throat (ENT) surgeon standing by if a tracheostomy becomes necessary.[15] Visualisation of the laryngeal inlet may be difficult. A bacterial swab of the epiglottis should be taken once the airway is secure. Antibiotic treatment with an extended-spectrum cephalosporin (e.g. ceftriaxone) is indicated. Recovery usually occurs about 48 hours after the institution of antibiotic therapy and is confirmed by visualisation of a normal epiglottis on laryngoscopy.

Bacterial tracheitis

Bacterial tracheitis is uncommon. The condition may occur at any age. The usual pathogens are *S. aureus, H. influenzae,* streptococci and *Neisseria* species.[16]

The signs and symptoms of bacterial tracheitis are frequently intermediate between those of viral croup and epiglottitis. Coughing produces copious tracheal secretions and retrosternal pain. The voice may be hoarse and stridor prominent. The larynx, trachea and bronchi can become acutely obstructed with purulent debris and inflammation with adherent pseudomembranes overlying friable tracheal mucosa.

Most patients with bacterial tracheitis will require tracheal intubation.

At laryngoscopy, the epiglottis and supraglottic structures will appear normal, although slough and pus may be visible beyond the vocal cords. Significant pneumonia and systemic symptoms of bacterial septicaemia are not unusual. Ceftriaxone is a reasonable first-line antibiotic therapy. The average duration of tracheal intubation is 6–7 days and antibiotic therapy and hospitalisation may be required for up to 14 days.

Diphtheria

Diphtheria is extremely rare as the UK has had a vaccination programme since the 1940s. It is caused by *Corynebacterium diphtheriae* and *Corynebacterium ulcerans* . It begins with a croup-like illness, cough and sore throat, but often progressing to death through sepsis, suffocation by the ‘pseudomembranes’ of serocellular exudate and direct effects of the powerful exotoxin, which has an affinity for neural endings (paralysis), cardiac muscle (heart block and myocardial failure) and the adrenal glands (hypotension with endocrine failure). Unless there is a high index of suspicion, it is a diagnosis easily missed. Treatment includes the administration of specific antitoxin and appropriate antibiotics.

Respiratory papillomatosis

Respiratory papillomatosis is characterised by recurrent proliferations of squamous papillomata within the airway, anywhere from lips to lungs. The viral pathogen is most commonly human papillomavirus types 6 and 11. The recurrent nature of this condition often necessitates multiple surgical procedures. The current management philosophy is toward a more conservative approach, aimed at ameliorating airway symptoms while limiting subsequent scarring of the larynx. Surgical debulking is the treatment of choice and several modalities have been used, including cold steel dissection, microdebridement, suction diathermy, cryotherapy, CO_2 or other laser ablation and radiofrequency cold ablation.

Any of these may be followed by systemic administration or direct injection of antiviral agents (e.g. cidofovir) into the resection sites, with the aim of reducing the frequency of reoperative surgery for recurrent papillomas.[17]

Bevacizumab is a monoclonal antibody that inhibits angiogenesis and tumour growth by targeting vascular endothelial growth factors. This drug has been used as an adjuvant to surgical management.[18]

Trauma

Inhalational Burns

Inhalational injury should be suspected with burns occurring in a closed space, and when facial burns, singed nasal hairs and oropharyngeal carbonaceous material are present. Respiratory complications are the major cause of mortality in children who are burnt. Direct airway burns or inhalation of products of combustion may lead to rapidly progressive oedema. The situation may be compounded by small airway and lung injury and by the need to provide adequate analgesia. Early intubation is strongly recommended prior to an emergency situation developing. Tracheal tube fixation is critical and may be problematic with extensive facial burns; it may require suturing of the tube to the nasal septum or securing the tube to the teeth.

Foreign Body Aspiration

Foreign body aspiration is one of the leading causes of death in children. It is most common in those under 3 years but can occur at any age.[19] Most deaths occur at the time of aspiration due to complete upper airway obstruction. Of those children who reach hospital, the mortality is low.[20] The most common aspirated object is ‘food’, usually nuts. Peanuts account for one-third of all foreign body aspirations.

Often the inhalation event is not witnessed, and the history may be less clear than expected. Presentation varies from severe acute upper airway obstruction through to a well, pink child with a persistent cough.

More than 90% of foreign bodies lodge below the upper airway in the main bronchus, slightly more commonly on the right side in children.[21]

As most of the inhaled material is organic in origin, a plain radiograph may fail to demonstrate an abnormality, especially in the first 24 hours, although X-rays in inspiration and expiration may show evidence of gas trapping.[19]

Management is as per the ‘choking child’ basic life support algorithm. Children with an effective cough should be closely observed and encouraged to cough by themselves. If the cough is not effective and the child is conscious, the rescuer may intervene with five back blows followed by five chest thrusts (or abdominal thrusts in older children).

If the child is not conscious, the child should have airway, breathing and circulation assessed and managed as per the basic life support guidelines, with assisted ventilation and chest compressions.

Most children who reach hospital with an inhaled foreign body, or the possibility of such, should have a rigid bronchoscopy under general anaesthesia.[22] Most anaesthetists will use an inhalational induction with sevoflurane to maintain spontaneous ventilation. Nitrous oxide is avoided, particularly if there is radiological evidence of gas trapping. The vocal cords and upper trachea are sprayed under direct laryngoscopy with 4 mg/kg lidocaine. Maintenance of ventilation and oxygenation during rigid bronchoscopy in children is controversial. The options are a spontaneous breathing technique (reduces the chance of distal movement or dislodgement of the foreign body) or muscle relaxation and the use of positive-pressure ventilation (reduces atelectasis and desaturation episodes). It is difficult to demonstrate the superiority of one technique over another. [20]

Subglottic Stenosis

Subglottic stenosis may be congenital or acquired (usually due to post-intubation laryngeal injury). The main feature is chronic, inspiratory stridor often made worse by intercurrent viral respiratory tract infection. When a child presents acutely, the management is as for croup. However, an ENT referral is necessary for diagnosis and management. The surgeon will grade the severity of the stenosis according to the size of endotracheal tube that can pass relative to that expected for age. This assessment and clinical condition will inform the decision to intervene. [23]

Treatment options available include inhaled or oral steroids to reduce inflammation and balloon dilatation of the narrowed airway with minimal mucosal trauma. Symptoms are resolved or improved in up to 70% of cases. If this fails, a laryngotracheal reconstruction (LTR) whereby a cartilage graft, from either the costal cartilages or the thyroid cartilage, is inserted into a vertical laryngotracheal fissure to expand the stenotic segment. Some stenoses will also require a posterior graft inserted into a posterior cricoid chondrotomy. In a double-stage LTR, a tracheostomy is inserted to safeguard the airway postoperatively and the grafted area is stented for approximately 6 weeks. A further procedure is then performed to remove the stent and assess the airway. A tracheostomy is not used in a single-stage LTR, and the child is left intubated with an age-appropriate endotracheal tube for 5–7 days postoperatively, both stenting and safeguarding the airway. All patients receive antireflux medication postoperatively to negate the negative impact of gastric contents on mucosal healing.

Congenital

Pierre–Robin Sequence

The Pierre–Robin sequence is a congenital anomaly presenting with micrognathia, glossoptosis and a cleft palate. Although there is a spectrum of airway obstruction most children can be managed by conservative measures or with a nasopharyngeal airway for a few months. The natural history shows that, with normal growth, airway compromise resolves without immediate surgical intervention as previously advocated. However, a few children do require tracheostomy. [24]

Cystic Hygroma

Conspicuous at birth, cystic hygroma or lymphangioma is a relatively rare cause of upper airway obstruction in infancy. The tumours consist of masses of dilated lymphatic channels. They usually occur in the neck but may involve tissues of the tongue and larynx, and occasionally extend into the mediastinum. Airway obstruction may be due to infection or haemorrhage into the lesion. Surgical excision has been the mainstay of treatment, although complete removal is difficult, and recurrence is common. Although some authors have reported watchful waiting for cystic hygroma, it should be considered only in patients who are asymptomatic. The medical treatment consists of the administration of sclerosing agents.

Laryngomalacia

Laryngomalacia is the commonest cause of congenital stridor and usually presents within the first 2 weeks of life. Clinicians should not give this diagnosis without full airway assessment to any baby with life-threatening symptoms or stridor that is obvious at birth. Airway obstruction results from the collapse of supraglottic structures on inspiration, and expiratory symptoms are not a feature. Stridor often gets worse initially for 6–9 months before gradually improving, with most children being free of symptoms by 18–24 months. [25]

It is a dynamic condition and the supraglottic collapse is most obvious during the ‘waking phase’ of anaesthesia if a formal airway assessment is done.

Most children will not require surgical intervention, but the remaining 5%–10% require some form of surgical treatment. Surgical options include division of the aryepiglottic folds to ‘open’ the constricted supraglottis, resection of the redundant mucosa and suspension of the prolapsing epiglottis to uncover the laryngeal introitus. A degree of gastrooesophageal reflux disease is often associated with laryngomalacia, and all children should therefore receive antireflux medication. This possibly reflects changes in airway and intrathoracic pressures in response to the airway obstruction, as opposed to being a causal factor. A neurological form of the condition exists and may be seen in children with neurological or neuromuscular conditions, such as cerebral palsy. In such cases, surgical intervention should be approached with caution, and it may be most appropriate to manage severe airway collapse with a tracheostomy. [26]

Other

Infantile Haemangioma

Infantile haemangiomas are the most common tumours of infancy, affecting approximately 1 in 10 children. [27] These are highly proliferative vascular tumours that may grow very quickly, causing obstruction when the airway is involved; if these are left untreated there is a 50% mortality rate. Most airway haemangiomas will co-exist with cutaneous lesions (but not vice versa). [28] The PHACES syndrome comprises airway haemangiomas with associated deep or diffuse cutaneous, segmental haemangiomas as well as posterior fossa malformations, arterial anomalies, cardiac/aortic defects, eye anomalies and a sternal defect. [29]

Medical and surgical interventions have included steroids, chemotherapeutic agents (vincristine, interferon-α), laser treatment, surgical excision, tracheostomy or a combination of these, but the spectacular effect of propranolol on cutaneous haemangiomas of infancy was described for the first time in 2008 [30] and confirmed by a meta-analysis as being the best treatment available for infantile haemangiomas. [31] The mean dose of propranolol was 2 mg/kg/day (range 0.5–3 mg/kg/day). The mean treatment duration was 6 months (range 1.5–10 months). Clinical improvement was seen in the range of 24 hours to 3 weeks (mean 3.8 days). Complications related to propranolol usage were found in one child (2.94%) who developed bronchoconstriction during the first week of treatment. Because of the possible side effects of propranolol, current infantile haemangioma treatment centres recommend that a full cardiovascular and respiratory review be performed prior to initiation of therapy.

Vocal Cord Palsy

Vocal cord palsy may be idiopathic, a result of a neurological abnormality, or traumatic (birth or iatrogenic). [32] It may be uni- or bilateral.

Unilateral palsy presents with stridor and dysphonia, which often resolves with time as the contralateral vocal cord compensates.

Bilateral vocal cord palsy is potentially life threatening, and a tracheostomy may be necessary in approximately half of the cases. Magnetic resonance imaging of the brain is mandatory to exclude an Arnold–Chiari malformation with hydrocephalus. [33] Spontaneous recovery rates of up to 70% are reported. [32]

Anaesthesia for Relief of Upper Airway Obstruction

The principle behind the safe induction of anaesthesia in the obstructed airway is the maintenance of spontaneous ventilation. Muscle relaxants should be avoided before the airway is secured to avoid the potentially disastrous ‘can’t intubate, can’t ventilate’ scenario.

A gaseous induction using 100% oxygen with sevoflurane is the technique of choice. The aim is to attain a plane of anaesthesia that is deep enough to allow laryngoscopy, but this is a slow process. Laryngoscopy may be direct or by videolaryngoscopy which is emerging as a tool of choice as it provides a better view, allows for teaching and has a greater success rate. [34] If the airway becomes obstructed following loss of consciousness, it can be improved by applying continuous positive airway pressure, changing the patient’s position (lateral or semi-prone position) and using simple airway manoeuvres or simple airway adjuncts, such as a nasal airway.

Sufficient depth of anaesthesia for laryngoscopy may not be achieved because of the obstructed airway. A laryngeal mask airway may help. If it is impossible to secure the airway, then direct access to the trachea via a cricothyroidotomy or tracheostomy should be gained.

Important points are:

- A prepared induction should be undertaken with efficient suction apparatus, a range of tracheal tubes, suitable stylets, bougies, trained staff, full monitoring, etc.
- Induction in the adopted position, for example sitting in epiglottitis, is advocated. The child is laid flat after induction and prior to intubation.
- Care must be taken not to distend the stomach as this will compound difficult ventilation.
- Orotracheal intubation is quickest and safest and should be performed initially. After adequate tracheal suction, the tube can be changed to a nasotracheal one. Muscle relaxants may be used at this point if the operator is confident of the ability to intubate and/or ventilate. [35]

Care of the Secured Airway

Successful management of upper airway obstruction in children requires optimal care of the nasotracheal tube. Such children must always be nursed in a paediatric intensive care unit with adequate nursing ratios. The nasotracheal tube must be positioned at the level of the clavicular heads (T_2) on chest X-ray. A meticulous technique of fixation must be employed to prevent accidental extubation. Adequate humidification is important to prevent obstruction of narrow tubes by secretions.

Repeated suctioning of secretions is required. Instillation of saline (0.5–1.0 mL) prior to suction may be necessary to encourage the removal of secretions. Light sedation is used to improve tolerance of the tracheal tube and to reduce the risk of self-extubation. Arm restraints may also be advisable, particularly in very young children.

In the event of clinical deterioration after intubation, a simple mnemonic may aid successful management; DOPES represents *d* isplacement of the tube, *o*bstruction of the tube, *p*neumothorax, *e*quipment failure and *s*tomach distension.

A true ‘can’t intubate, can’t ventilate’ scenario is rare in children. More often the situation has arisen due to ‘operator error,’ for example suboptimal positioning of the child, inadequate anaesthesia, a distended stomach, a blocked endotracheal tube or understandable panic. However, the only objective in this situation is to maintain oxygenation and if none of the basic manoeuvres resolves the situation the options are to perform a needle cricothyrotomy or a formal tracheostomy.

Tracheostomy

Tracheostomy remains a life-saving procedure and must be undertaken if tracheal intubation is impossible. It is best performed under general anaesthesia with the neck extended. The airway can be maintained by a facemask or laryngeal mask airway. Tracheostomies have been formed under local anaesthesia.

Care of a newly created tracheostomy is similar to that of an endotracheal tube, with the additional problem of some discomfort and the likelihood of fresh blood in the airway. Stay sutures in the tracheal wall lateral to the incision aid recannulation if accidental dislodgement occurs prior to the formation of a well-defined tract.

The first tracheostomy tube change is undertaken once a tract has been established, usually between 5 and 7 days.

Needle Cricothyroidotomy

Cricothyroidotomy is the creation of an opening in the space between the anterior inferior border of the thyroid cartilage and the anterior superior border of the cricoid cartilage, to gain access to the airway below the glottis. It is difficult and risky for a small child. There are purpose-made paediatric kits available, and these should be immediately available in every paediatric anaesthetic room.

Newer cannulae have both a 15 mm and a Luer-lock connector. It is not possible to ventilate a patient with a self-inflating bag via a needle cricothyrotomy and the cannula should be connected via the Luer-lock connection to an oxygen flowmeter via a Y-connector. The oxygen flow rate is initially set at the child's age in years. Ventilation occurs by occluding the open end of the Y-connector with a thumb for 1 second. If this does not cause the chest to rise, the flow should be increased by increments of 1 L/min.

Expiration must occur via the upper airway, even in situations of partial upper airway obstruction. If upper airway obstruction is complete, the gas flow must be reduced to 1–2 L/min. This will provide some oxygenation but little ventilation. Insufflation will buy a little time in which to secure a surgical airway. Complications include bleeding, pneumothorax, pneumomediastinum, subcutaneous emphysema, tracheoesophageal fistula, infection, haematoma and catheter dislodgement.

The recent national audit of major complications of airway management in the United Kingdom showed that the 'can't intubate, can't ventilate' scenario is rare in paediatric practice. Cricothyroidotomy and jet ventilation are difficult and risky, with the only reported attempt being unsuccessful. Tracheostomy by an ENT surgeon has been used successfully more often. [36]

Acute respiratory distress in children

Tavey Dorofaeff and Mark Graeme Coulthard

Introduction

Acute Respiratory Failure in Children

Acute respiratory failure in children, as in adults, is a failure of gas exchange; inadequate oxygenation and carbon dioxide clearance. Respiratory distress refers to both the sensation of breathlessness and the signs of increasing effort to breathe as a consequence of deteriorating gas exchange or as a compensatory response to acidosis. The age-related norms of respiratory rate are listed in Table 92.1 . Tachypnoea may present with or without associated signs and symptoms of increased work of breathing such as intercostal muscle use, accessory muscle use, tracheal tug and ‘grunting’ at end expiration. These are some of the sentinel signs and symptoms of respiratory distress in children (Box 92.1).

Table 92.1

Normal heart and respiratory rates relative to age for hospitalised children

AGE GROUP	RESPIRATORY RATE MEAN (5th–95th PERCENTILE)	HEART RATE MEAN (5th–95th PERCENTILE)
0–3 months	41 (27–62)	140 (113–171)
3–6 months	38 (25–58)	135 (108–167)
6–9 months	35 (23–54)	131 (104–163)
9–12 months	33 (22–51)	128 (101–160)
12–18 months	31 (21–48)	124 (97–157)
18–24 months	29 (20–45)	120 (92–154)
2–3 years	27 (18–42)	115 (87–150)
3–4 years	25 (18–40)	111 (82–146)
4–6 years	24 (17–37)	106 (77–142)
6–8 years	23 (16–35)	100 (71–137)
8–12 years	21 (15–31)	94 (66–129)
12–15 years	19 (13–28)	87 (61–121)
15–18 years	18 (13–25)	82 (57–115)

Box 92.1

Causes of respiratory failure in children

Common causes of respiratory failure in the neonate

Congenital
Respiratory distress syndrome of prematurity
Congenital heart disease
Laryngo/tracheo/bronchomalacia
Vascular rings and slings
Diaphragmatic hernia
Pulmonary hypoplasia
Gastroschisis and omphalocele
Neuromuscular and skeletal disorders
Acquired
Transient tachypnoea of the newborn
Meconium aspiration syndrome
Neonatal pneumonia
Pulmonary haemorrhage
Diaphragmatic palsy

Common causes of respiratory failure beyond the neonatal period

Bronchiolitis
Pneumonia
Asthma
Croup
Tumours
Trauma
Acute-on-chronic respiratory failure with chronic neuromuscular conditions
Acute respiratory failure with acute neuromuscular conditions
Acute respiratory distress syndrome

Respiratory failure related to immunocompromised host

Epidemiology

Data extracted from the Australian and New Zealand Intensive Care Society (ANZPIC) database [1] show that bronchiolitis, pneumonia, asthma and laryngotracheobronchitis (croup) were the top respiratory diagnoses for the years 2013 to 2022 and will likely continue to be so in the future. Of all admissions in 2022, approximately 50% required some form of respiratory support. Approximately a third of these had respiratory pathology and over half of those required respiratory support. The commonest mode of respiratory support was high-flow nasal cannula (HFNC) oxygen (59.8%) for respiratory illnesses. Overall, the invasive ventilation rate was 33.3% and 16.6% in the top listed respiratory diagnoses. This has fallen from 21.1% in 2013. The mean length of stay for respiratory admissions was 3.6 days. In comparison, the length of stay for an elective admission was 1.6 days. Overall PICU mortality is reported at 2.2% for 2022, averaging between 2.0% and 2.5% for the years 2013 to 2022. PICU mortality is low when compared to adult intensive care. This is one of the fundamental differences that sets the specialties apart.

Differences in the Respiratory Mechanics of Children

Neonates and small infants have a higher resting metabolic requirement for oxygen, which is estimated to be 7 mL/kg/min compared to 4 mL/kg/min for a school-age child or an adult.

Neonates and small infants have many differences compared with adolescents and adults which puts them at a disadvantage. [2-4]

Specific differences in neonates and infants:

- Diaphragmatic breathers
- Reduced diaphragmatic muscle mass
- Fewer fatigue-resistant muscle fibres

- Compliant rib cage
- Reduced ability to generate negative pleural pressures
- Primary mechanism to increase minute ventilation is by tachypnoea alone with limited ability to increase tidal volume
- Lung volume close to functional residual capacity (FRC) at end expiration
- Tendency for airways to collapse at end expiration.

As children grow the issues that affect neonates, infants and toddlers change as the child develops an upright body habitus.

The airways of all children are disproportionately smaller than an adult's. Any obstruction of the lumen of the airways with increased mucous production or bronchoconstriction also increases airway resistance to the fourth power of the radius (Hagen–Poiseuille equation: $\Delta P = 8\mu LQ/\pi r^4$ where ΔP is the pressure reduction, L is length, Q is volumetric flow rate and r is radius). Hence, anatomically small airways are a distinct disadvantage. This is particularly the case in neonates and infants but applies across the age (and size) range.

Clinical Features

Signs and Symptoms of Acute Respiratory Failure

Signs and symptoms of respiratory failure in neonates and children are not subtle and are usually apparent from a brief focused clinical exam of the respiratory system. They reflect the developmental ability of the neonate or child to compensate for respiratory failure.

Primarily as a result of pulmonary mechanics, neonates and small infants tend to become moderately to severely tachypnoeic with hypoxia and hypercapnia. Premature babies, term babies and very young infants can manifest apnoeas. These may or may not be present with increased work of breathing. The cause of apnoea is not fully understood but is thought to relate to immaturity and inability to respond or maintain a compensatory tachypnoea. Bradycardia is associated as a secondary consequence of the hypoxia that develops. Older children have very similar features in respiratory distress and respiratory failure to adult patients.

Physical Examination

Respiratory examination findings are more challenging to elucidate in an active child who may be uncooperative or acutely distressed. In addition, the rate of breathing is much faster. A physical exam requires a skilled physician with knowledge and experience. With practice, skills in observation, auscultation and percussion can be developed. As a rule, a truncated ‘adult’ type of exam that is limited to inspection and auscultation will give the examiner the best information whilst limiting distress to the child. Most of the information of benefit to the intensivist will be obtained by observation, specifically the respiratory rate, work of breathing and pulse oximetry.

Children with neuromuscular conditions may not have a compensatory tachypnoea and have limited ability to compensate. Clinical signs may not be present and they do not adapt in the same way as a child with few comorbidities.

Neonatal Period

Introduction

There are a number of conditions that present in the neonatal period [5] that do not have correlates in adult medicine. They primarily relate to disorders of lung maturity, lung growth, lung malformation and adaption to extrauterine life.

Definitions

There is some complexity in the description of prematurity, gestation and birthweight. It is briefly described as follows [6] :

- a term newborn is delivered 37 weeks after the mother’s last menstrual period; prematurity occurs when a newborn is less than 37 weeks of completed gestation
- extremely low birth weight (ELBW) is less than 1000 g
- very low birth weight less than (VLBW) 1500 g
- low birth weight is less than (LBW) 2500 g
- small for gestational age is less than 5th percentile of weight for gestational age.

Prematurity and Neonatal Chronic Lung Disease

The lungs develop throughout the fetal period until late childhood. Lung development is divided into five stages: embryonic, pseudoglandular, canalicular, saccular and alveolar. The embryonic and pseudoglandular phases have very little gas exchange ability. At 28 weeks of gestation, the middle of the canalicular stage, a significant amount of ventilation can occur within the respiratory bronchioles; 28–32 weeks corresponds to the saccular stage. At around 32 weeks, gestation intrinsic surfactant production begins.[7] In preparation for premature birth this may be stimulated by the administration of corticosteroids to the mother. This is conventional therapy for any mother with threatened delivery prior to 32 weeks. Additional factors, such as fetal stress and infection, will also augment alveolar development.

Total alveolar surface area continues to increase beyond 32 weeks and continues into childhood. This is the result of increasing maturity of alveoli, replication and increasing numbers.

All babies born with any significant amount of prematurity (i.e. <35 weeks) or low birthweight will likely require newborn intensive care and respiratory support.

Chronic neonatal lung disease (CNLD) is defined as[8]:

- oxygen requirement at 28 days post-delivery (irrespective of premature gestation), or
- oxygen requirement at 36 weeks of gestational age and

- an absence of an alternative diagnosis

Bronchopulmonary dysplasia and hyaline membrane disease are pathological findings on biopsy or autopsy of premature infants who have respiratory failure. They are often used synonymously to describe CNLD and respiratory distress syndrome. The pathological features of CNLD include alveolar septal fibrosis with alternating collapse and hyperinflation of acini. Smooth muscle hypertrophy/hyperplasia may also be present. Chest X-ray (CXR) may reveal generalised hyperinflation, multiple cystic areas and opacities. A novel type of CNLD exists (Wilson-Mikity syndrome) where babies may not have an initial oxygen requirement but go on to develop an oxygen requirement towards term or beyond.

Complications of prematurity are a common comorbidity in children admitted to a paediatric intensive care unit (PICU) later in life with respiratory failure. [9] This is frequently in the context of an acute viral chest infection. There may also be present pulmonary hyper-reactivity and pulmonary hypertension or recurrent asthma in older children.

Apnoea is a feature of prematurity and is a common symptom of illness in premature infants from birth until about 3 months of corrected age. Important differential diagnoses include sepsis (bacterial and viral), intraventricular haemorrhage and pain. Respiratory stimulants, such as caffeine, can be used to treat apnoea, though this is not always effective. Quite often the infant will need non-invasive support, such as HFNC oxygen, continuous positive airway pressure (CPAP) or bi-level positive airway pressure (BiPAP). Ultimately invasive ventilation may be needed to manage the underlying condition and the apnoeas.

Central hypoventilation due to a *PHOX2B* mutation is increasingly recognised as a congenital form of depressed ventilatory drive beyond the neonatal period. It manifests as hypoventilation during sleep. These children usually need non-invasive or invasive support. If undiagnosed, these children can present as sudden infant deaths.

Maternal tobacco use during pregnancy is a significant cause of prematurity, and it impairs lung development. Environmental tobacco smoke exposure exacerbates chronic lung disease, asthma and recurrent bronchiolitis in older infants.

Pulmonary Hypoplasia

This can be primary idiopathic or secondary to a space-occupying lesion within the chest, which limits room for lung development and results in abnormal pulmonary vasculature and pulmonary hypertension. Congenital diaphragmatic hernia (CDH), cystic adenomatous malformation, congenital neuroblastoma and great vessel abnormalities are common causes. Depending on the residual lung function it can have a spectrum of clinical significance from an incidental finding to the requirement for long-term respiratory support.

Acquired Neonatal Diseases

Transient Tachypnoea of the NewBorn

Transient tachypnoea of the newborn (TTN) is short-lived delayed clearance of fetal lung fluid. In the transition from intrauterine life, the infant has to aerate the majority of its alveoli within a few minutes. Some infants may be slow to progress through this process. It is often an issue in infants that have little exposure to catecholamines due to rapid operative delivery. Although these infants may require oxygen or CPAP, it is seldom that they need invasive ventilation.

Meconium Aspiration Syndrome

Meconium is the term used to describe faecal material of an infant prior to and in the first days of life. Passage of meconium is normal after birth. Passage of meconium prior to or during birth is an indicator of fetal stress. If inhaled or aspirated by the infant during delivery it induces a chemical pneumonitis and obstructive lung disease. If there is meconium present and if the neonate is apnoeic, it is recommended that he/she be suctioned below the vocal cords before bag-mask ventilation. Either intubation and suction via the endotracheal tube (ETT) or the use of a specialised meconium aspirator is recommended.

Non-invasive respiratory support and invasive ventilation are standard treatment options. Antibiotics are commonly administered as there is concern that sepsis might be an additional cause of fetal distress. Natural lung surfactant is deactivated by meconium. However exogenous surfactant therapy has not been shown to improve overall survival, but it may reduce hypoxia, though it can be poorly tolerated. There are conflicting recommendations regarding its use.

Extracorporeal life support (ECLS) is indicated for severe meconium aspiration syndrome (MAS). Of all disease entities treated with ECLS (including all neonatal, paediatric and adult causes), MAS has the greatest survival. The Extracorporeal Life Support Organisation (ELSO) database figures show that survival from severe respiratory failure due to MAS is upward of 90% with some units boasting near-100% survival.

Neonatal Pneumonia

Neonates are at risk of pneumonia [10] due to the relative immaturity of their immune system. They are especially at risk from encapsulated bacteria and Gram-negative bacteria, such as *Escherichia coli* , *Klebsiella* and *Serratia* . Group B *Streptococcus* is carried as a vaginal commensal by up to 50% of women so is a common neonatal pathogen. This organism also causes sepsis and meningitis in infants and newborns. Early infections less than 14 days are likely to have come from the mother at birth, prior to delivery (chorioamnionitis, prolonged rupture of membranes) or by transplacental infection (*Listeria monocytogenes*). Later infections are acquired from the infant’s commensal flora.

Viruses, such as cytomegalovirus, varicella and other herpes viruses, tend to cause a generalised viraemia rather than isolated pneumonia. Fungal and protozoan infections are a rare causes of neonatal pneumonia and tend to cause a CNS or systemic infection.

Pulmonary Haemorrhage

Prematurity, surfactant deficiency and persistent fetal circulation with pulmonary hypertension all predispose an infant to the risk of pulmonary haemorrhage. Haemorrhagic disease of the newborn secondary to Vitamin K deficiency can also present with pulmonary haemorrhage. However, gastrointestinal bleeding and intracerebral bleeding are far more common. Children with abnormal pulmonary vascularity of the bronchial arteries can also present with catastrophic pulmonary haemorrhage; however, this tends to present later in life. Disseminated intravascular coagulation can result in pulmonary haemorrhage in the setting of severe multi-organ failure.

Congenital Heart Disease

Many congenital cardiac lesions present with respiratory features.[11] Careful examination will help to elucidate the presence or absence of congenital heart disease. Features to look for include:

- Cyanosis
- Tachypnoea
- Tachycardia
- Hepatomegaly
- Murmurs, heaves and thrills in the precordium
- Absent femoral pulses
- Plethora or oligaemia on chest radiography
- No improvement in cyanosis with supplemental oxygen
- Acidosis/lactataemia.

Although antenatal ultrasound scanning detects a significant number of lesions, early discharge or home birth means that symptoms can develop or remain undetected until acute decompensation occurs.

Congenital heart lesions producing acute respiratory failure are likely to fall into one of the groups listed below:

- *Left heart obstruction (e.g. critical aortic stenosis, interrupted aortic arch and coarctation of the aorta):* this leads to pulmonary oedema, reduced pulmonary compliance and respiratory failure.
- *Large left-to-right shunts (e.g. ventricular septal defect and patent ductus arteriosus):* excessive pulmonary blood flow can cause pulmonary oedema, airway compression and obstruction. Minor intercurrent infection results in decompensation.
- *Cyanotic lesions:*
    - there is an obstruction to pulmonary blood flow (e.g. tetralogy of Fallot (ToF) and critical pulmonary stenosis)

- the pulmonary and systemic circuits are in parallel (e.g. transposition of the great arteries (TGA))
- there is complete mixing of systemic and pulmonary blood (e.g. single ventricle and truncus arteriosus)
- pulmonary venous abnormalities such as total anomalous pulmonary return (TAVPR).

Early institution of intravenous prostaglandins is important in newborns along with other supportive measures, such as intubation, ventilation, judicious fluid therapy and inotropes. There are no contraindications to the commencement of prostaglandins in a collapsed infant where a paediatric cardiologist is not available to make an immediate assessment. Total anomalous pulmonary venous drainage is one lesion where prostaglandin use most likely will be ineffectual. Occasionally it can worsen the cyanosis. This diagnosis requires expert assessment that is not immediately available to many collapsed infants at their initial presentation.

Respiratory Complications of congenital heart disease

Vascular Rings and Slings

Vascular rings and slings [12], [13] may be considered complete or incomplete and result from aberrant vessels and the ductus arteriosus (or ligamentum arteriosus if the duct is closed) leading to a constricting lesion of the trachea or bronchi. The most common type of sling is the pulmonary artery sling: an anomalous left pulmonary artery and the ductus encircling the trachea posteriorly. Vascular rings most commonly result from a right-sided aortic arch or a double aortic arch. There are a number of combinations: double aortic arch and derivatives causing complete ring, right-sided aortic arch and anomalous right subclavian artery, right-sided aortic arch, mirror image vessel branching and left ductus arteriosus and an anomalous innominate artery.

The result of slings and rings can be malformation of the underlying airways. Resulting airway obstruction requires surgical correction of the vascular compression. Tracheobronchomalacia often remains once the obstruction is relieved if the lesions have led to a secondary malformation of the airway; this can lead to significant morbidity.

Complications of Cardiac Surgery

Diaphragmatic Palsy

Palsy of the diaphragm is almost exclusively a complication of cardiothoracic surgery. These infants are difficult to wean from ventilation. If there is paradoxical upward movement of the affected diaphragm during inspiration surgery to plicate the diaphragm is required. This stabilises the affected hemidiaphragm so the normal hemidiaphragm and intercostal muscles can still create negative pleural pressure for inspiration. The palsy will often improve with time.

Recurrent Laryngeal Nerve Palsy

Palsy of the recurrent laryngeal nerve results from an inadvertent injury sustained from surgery within the central structures of the chest. The most clinically significant manifestation is paresis of the ipsilateral vocal cord. Normal vocal cord function is necessary to maintain airway patency. Unilateral paresis is tolerable, but bilateral paralysis is poorly tolerated, sometimes resulting in recurrent extubation failure. Occasionally, a tracheostomy is needed to maintain a patent airway; fortunately, this is an uncommon situation.

Congenital Diaphragmatic Hernia

There are two types.[14], [15]

Bochdalek Hernia

A Bochdalek hernia involves a deficiency in the postero-lateral part of the diaphragm. Most occur on the left side. A variable amount of the abdominal viscera herniates through into the chest. The presentation is dependent upon whether a hernia is diagnosed antenatally or not and whether pulmonary hypoplasia and pulmonary hypertension are present. Antenatal diagnosis may allow for the use of fetal intrauterine therapy; however, this is still experimental. The spectrum of clinical course ranges from profound, non-survivable hypoxia and pulmonary hypertension in the newborn to mild tachypnoea in infancy or an incidental finding diagnosed when a child comes to medical attention. Therapy involves respiratory support as appropriate and surgical closure of the defect. Children with severe respiratory failure may need extensive medical stabilisation with high-frequency oscillatory ventilation (HFOV), nitric oxide therapy and extracorporeal life support (ECLS). About 10% of children with CDH have a chromosomal abnormality.

Morgagni Hernia

A Morgagni hernia is in the anterior diaphragm. Typically, only the bowel will herniate through the defect. It is extremely uncommon for this hernia to cause respiratory compromise. It is often an incidental finding or is associated with mild respiratory disease. Clinically significant hernias are repaired electively.

Laryngomalacia/Tracheomalacia/Bronchomalacia

This results from cartilaginous weakness of the larynx, trachea, main bronchi or any combination of these.[16], [17] There may be malacia at single or multiple levels. Laryngomalacia is usually primary in nature. Tracheomalacia and bronchomalacia can be primary or secondary and are caused by intrinsic anatomical abnormalities of the airways or secondary to external factors causing distortion or compression of the airways. Abnormalities of size or path of mediastinal blood vessels (primarily the aorta, pulmonary artery and right subclavian artery) and chest masses are the most common. The result is a ‘floppy’ airway that tends to collapse during inspiration and/or expiration. Depending on whether these segments are intra- or extrathoracic, stridor (extrathoracic) and/or wheeze (intrathoracic) will be present. Respiratory embarrassment may range from mild to severe, including severe decompensation from acute airway obstruction and so-called ‘malacic’ spells. These can be exacerbated by viral infections.

Severe long-segment malacia can be an indication for long-term non-invasive home ventilation or tracheostomy and invasive ventilation. Over the first 18–24 months of life, there is growth of the cartilage and improvement in the airway rigidity. Tracheopexy (suspending the trachea on the sternum) and tracheal stenting are possible alternative interventions. Where malacia is a secondary effect of another abnormality, surgery to correct this defect may be warranted (e.g. vascular slings or rings, pulmonary atresia with poststenotic dilatation of the pulmonary artery); however, malacia often persists post-surgical correction. Management can be complicated and prolonged. Supportive therapies in lieu of growth and maturity of the large airways are the most common approach.

Cystic Congenital Adenomatous Malformation (CCAM) and Pulmonary Sequestration

CCAM is a cystic mass of adenomatous tissue. These are usually detected antenatally, they are non-malignant or benign. They act as a space-occupying lesion in the chest and if large cause respiratory compromise. Pulmonary sequestrations are abnormally formed lung tissue that is not connected to the bronchial tree. Extralobar pulmonary sequestrations are said to be congenital in nature and present with respiratory distress. Intralobar pulmonary sequestrations occur more in children and adolescents and are thought to be the result of recurrent infections. For CCAM and sequestrations, the treatment is surgical removal.

Neuromuscular and Skeletal Disorders

Any disorder that affects the ability of the muscles to ‘drive’ the ventilatory pump, or that causes a chest wall deformity, can compromise the effectiveness of ventilation. [18] In the neonatal period these present with hypoventilation, desaturation and apnoea. Ventilator dependence as a neonate with these disorders indicates that the child is unlikely to survive without intensive support and, most likely, mechanical ventilation. Parents should be counselled appropriately. Spinal muscular atrophy (SMA) type 1 is the most common example of this. Less severe neuromuscular disorders may survive the neonatal period but go on to develop respiratory failure later (e.g. Duchene muscular dystrophy, SMA types 2 and 3). The amount of support offered needs to take into consideration ethical treatment, rational expenditure of resources and the wishes of the family and child (if appropriate).

Common Acquired Diseases Beyond the Neonatal Period

Bronchiolitis

Bronchiolitis is the most common cause of respiratory failure beyond the neonatal period in children (<1 year of age). Prematurity is a common comorbidity. [19] Data from the Australasian ANZPIC registry show that bronchiolitis is the primary emergent diagnosis leading to PICU admission. [1] Comprising 35%–40% of all PICU admissions in the years 2013–2022. Bronchiolitis is a common reason for inter-hospital transfer. High-flow oxygen therapy is the primary therapy and has increased in the years 2013–2022 from 71.8% to 87.3%. Increasingly it is used outside the PICU. Invasive ventilation rates within the PICU have remained at around 11% for the same years. Mortality has been low in all years (<0.5%).

Bronchiolitis is caused by infection and inflammation in the bronchioles resulting in obstructive lung disease leading to hypoxaemia, tachypnoea and air trapping. Chest radiographs show hyperinflation (and collapse) of lung segments and often right upper lobe collapse and/or consolidation. Respiratory syncytial virus (RSV) and human metapneumovirus (hMPV) are the most common viral pathogens. [20], [21] Additionally, bronchiolitis can be caused by the human bocavirus, adenovirus, parainfluenzae, influenza virus and rhinovirus families; all are implicated in the hospitalisation of children.

Treatment is primarily supportive, [22] with the majority of infants supported by non-invasive respiratory support (largely HFNC oxygen). [23], [24] Only a few infants require invasive ventilation due to the impact HFNC has had on the requirement for invasive ventilation.[23] They tend to be the very young infants in whom apnoea is a feature of the disease, and infants with underlying medical conditions, such as chronic lung disease, cardiovascular disease and neuromuscular disease.

Up to 30% of infants[25] who require invasive ventilation for bronchiolitis have a concurrent bacterial infection, so antibiotics are often started empirically in severe bronchiolitis until haematology, inflammatory markers become reassuring and cultures are negative.[25]

Steroids, epinephrine (adrenaline), bronchodilators and hypertonic saline have been investigated for the treatment of bronchiolitis. None has consistently shown significant benefit in hospitalised children.[22,25] Specific antiviral therapy is not indicated in the immunocompetent. Recombinant RSV antibody provides passive prophylaxis against RSV and is indicated in infants with chronic lung disease or congenital heart disease.

Pneumonia

ANZPIC data show that about 17% of respiratory admissions in 2022 were for pneumonia.[1] In the years 2013–2022 this has ranged between 11% and 17%.[1] The majority were treated with high-flow oxygen therapy (76%) in 2022. Invasive ventilation rates were 16.6% for 2022 and have been falling from 2013 (29.3%).

Community-acquired pneumonia is caused predominantly by the common respiratory viruses followed in frequency by staphylococcal and streptococcal bacteria. Atypical infections such as *Mycoplasma pneumoniae* and *Chlamydia* also feature.[26,27] Appropriate antibiotic therapy is vital.[28] Respiratory support is escalated as required to support the work of breathing and provide an acceptable gas exchange. High-flow oxygen therapy is the next most common therapy after supplemental low-flow oxygen and frequently all that is required.

If ventilation is required, current recommendations in paediatric acute respiratory distress syndrome (pARDs) (of which pneumonia is a secondary cause) should be followed. Tidal volume should be limited to less than 8 mL/kg with sufficient positive end-expiratory pressure (PEEP) to maintain lung distention. Open-lung ventilation with protective ventilation strategies is necessary to avoid secondary lung injury. Tidal volumes 6–8 mL/kg, PEEP of 5–10 cm H_2O and FIO_2 titrated to give oxygen saturations greater than 88%.[29]

Pulmonary secretions should be sampled to enable robust antibiotic stewardship. Bronchoscopy for samples is often not possible in children owing to the small calibre of the ETT. Blind bronchoalveolar lavage is almost routine for intubated patients. Endotracheal suction samples are also used; however, poor sensitivity and specificity limit their value.

Pneumonia is frequently complicated by a simple effusion or the development of a complex effusion in children.

Asthma

Asthma is frequently diagnosed in childhood. From the ANZPIC registry, asthma is the third leading cause of PICU admissions in children.[1] Static at around 13%–16% of all admissions for years 2013–2022. The use of invasive ventilation is very low. High-flow oxygen therapy and non-invasive ventilation (NIV) are the primary supportive therapies with bronchodilator and anti-inflammatory therapy.

Not all wheezy illnesses in children have asthma.[30] They may be manifestations of an acute viral illness that presents with a constellation of symptoms including wheezing and tachypnoea, but they do not respond to bronchodilators. As an intensive care physician, it is important to make an assessment of these patients regarding the underlying aetiology. The management of a wheezy lower respiratory infection is purely supportive but may often require non-invasive or invasive respiratory support. However, acute severe asthma requires aggressive bronchodilator and steroid therapy.

NIV with CPAP or bi-level airways pressure (BiPAP) is increasingly used in the management of asthma.[31,32] Asthma was thought to be a contraindication to these therapies, however, NIV is now considered to have a place in acute severe asthma. It should not replace invasive ventilation if this is deemed to be necessary. The approach taken for the ventilation of severe paediatric asthma is the same as for an adult patient. The reader is referred to the chapter on acute severe asthma in adults for the salient issues regarding ventilation of patients with asthma.

Acute Neuromuscular Disease

For the most part, the acute neuromuscular conditions that children succumb to are similar to those of adults. The reader is referred to the relevant chapters. Guillain–Barré, tetanus, botulism, acute demyelinating encephalomyelitis and acute spinal injury are supported with ventilation whilst expectantly awaiting the return of neurological function. In Australia, tick bite paralysis can cause severe paralysis in children. The toxin binds covalently with the acetylcholine receptor complex. The cholinergic block lasts long after the source of the toxin is removed. Quite often, children require prolonged courses of supportive ventilation and intensive care. This is in contrast to the North American tick where paralysis resolves relatively quickly.

Chronic Neuromuscular Conditions

Chronic neuromuscular disorders that are not diagnosed at birth are often diagnosed in infancy and early childhood. These children often require intermittent respiratory support with intercurrent illnesses. Many of these diseases are life-limiting and eventually children with severe neuromuscular or progressive conditions will suffer severe respiratory infections that need ventilation for prolonged periods. Cerebral palsy, Duchenne muscular dystrophy and spinomuscular atrophy are examples. Intubation can be difficult owing to scoliosis, limited jaw opening or facial dysmorphism. Ventilation is often troublesome due to chest wall deformity and underlying chronic lung disease. Weaning from ventilation is slow and careful and may involve a protracted stay for weeks in the PICU on invasive ventilation and NIV. Some children cannot be weaned from invasive ventilator support after a severe infection. End-of-life care and limitation of interventions are important issues to discuss with parents and caregivers.

Paediatric Acute Respiratory Distress Syndrome (pARDs)

pARDS may occur in children of all ages from a variety of direct and indirect lung insults, as it does in adults. [33-42] In children, common causes of pARDS include shock, pneumonia, sepsis and near-drowning.

pARDS consensus definitions and guidelines are reviewed periodically by the Pediatric Acute Lung Injury Consensus Conference (PALCC). Revised criteria were released in 2023. [37] The primary purpose of these criteria is to standardise research diagnostic criteria. The guidelines outlined several critical areas for research. Consensus statements were made where there was supporting evidence. Criteria encompass invasive and NIV and use both oxygenation index (OI), where arterial blood gases are available and oxygenation saturation index (OSI) where they are not. See Table 92.2 for details. pARDS as a primary diagnosis in children reported in the ANZPIC registry is very low (<1%). This reflects clinicians' conceptualisation of pARDS as a diagnosis versus a process clinically.

Table 92.2

Adapted from Paediatric Acute Lung Injury Consensus Conference (PALICC 2023). [43]

Treatment modalities for pARDS are very similar to those for adults with the open-lung/low-tidal-volume strategy, and acceptance of permissive hypoxia and hypercarbia. HFOV is commonly employed in contrast to adult practice. A large randomised trial has yet to prove HFOV superiority in children. ECLS is considered if there is a reversible or treatable cause.

Heart Disease

Acquired heart disease and the residual effects of congenital heart disease can occasionally be associated with respiratory distress. This generally occurs only where there is pulmonary over-circulation, pulmonary congestion and to a lesser degree advanced pulmonary hypertension.

Tumours

Neuroblastoma and lymphomas are the most common tumours that develop in children causing respiratory compromise. Lymphomas tend to arise centrally from mediastinal nodes. A rapidly growing mediastinal T-cell lymphoma is a true oncological emergency. Neuroblastomas arise from the thoracic sympathetic chain. These tumours generally are slower growing than T-cell lymphomas. Mediastinal compression results in life-threatening respiratory and cardiovascular compromise. Maintenance of spontaneous breathing and positioning the patient in a forward sitting position are simple measures that may improve ventilation. Children will often find their preferred position. Intravenous steroids may need to be commenced before diagnosis if the respiratory compromise is severe. Intubation of these patients is risky and best avoided. If it is required, it is best done in the operating theatre with gaseous anaesthetic induction and maintenance of spontaneous ventilation.

Support for Children With Severe Respiratory Failure

Supportive Care/Family-Centred Care

Even in the most critically ill children, parents are encouraged to be involved in the care of the child as much as is practical. [44] The calming influence of a parent or grandparent cannot be understated and is a valuable adjunct to sedation regimens in the PICU and the neonatal intensive care unit (NICU). By inviting parents to participate in the care of their critically ill child, a partnership is forged that promotes trust and compliance with necessary medical interventions. If the child does not survive, the benefit for the parents in the subsequent grieving process should not be underestimated. Siblings may also benefit. However, this must be matched with the needs of the patient.

Non-Invasive Respiratory Support

High-Flow Nasal Cannula Oxygen Therapy

HFNC oxygen therapy has made its way rapidly into the PICU armament of support.[23], [24], [45-62] In 2022 35.9% of patients received high flow oxygen therapy. This has increased from 22.1% in 2013 with a steady increase annually. HFNC oxygen therapy consists of a simple circuit comprising a gas flow regulator, an oxygen mixer, a humidifier and non-occlusive nasal prongs. The gas flow is matched to the peak inspiratory flow so the nasopharynx is continuously replenished with a fresh gas supply. A small but not insignificant amount of PEEP is the result. Flow would be prescribed at 2 L/kg and occasionally 3 L/kg.

Nasal and Face Mask Non-Invasive Ventilation

NIV can be used in all ages of patients.[63] PICU use of NIV runs at between 14% and 17% (2013–2022).[1] Nasal and face mask interfaces are most commonly employed. As patients grow, the facial architecture changes. Achieving a good fit and seal can be challenging. Newer designs and improved cushioning help. Older children, like adults, are most suited to mask ventilation support; however, with persistence and a range of masks, younger children can be supported with NIV.[63-66] Frequently sedation is required to enhance compliance.

Triggering and delivery of synchronised support can be challenging. Determining the best mode depends on the requirements of the patient and the abilities and limitations of available equipment.

CPAP and BiPAP are the commonest modes used. BiPAP is used with a flow trigger in PICU. Occasionally NAVA (neurally adjusted ventilatory assistance) is used. NAVA relies on a proprietary nasogastric tube that has electrodes that detect the electrical signal passing down the vagus nerve and over the diaphragm. The strength of this impulse is proportionate to the amount of ventilator support required by the patient. NAVA can be used in non-invasively ventilated and invasively ventilated spontaneously breathing patients.

The single most valuable resource, other than equipment is experienced personnel who are able to persevere, use alternative interfaces and understand the equipment to get the optimal patient synchrony, comfort and level of respiratory support.

Invasive Ventilation

Conventional Ventilation

The debate as to volume- or pressure-regulated ventilation in paediatrics is ongoing, although it appears that volume control may be more lung protective. This is only supported by meta-analysis of studies from premature infants.[67] The second Paediatric Acute Lung Injury Consensus Conference (PALICC-2)[68] and the European Paediatric Mechanical Ventilation Consensus Conference (PEMVECC)[69] do not support one mode over another. Pressure control ventilation has historically been used in children owing to early ventilators not being able to guarantee delivery of the small tidal volumes that babies and infants require. With newer, more sophisticated ventilators the volume control can be adjusted up to the nearest millilitre. Accurate volume measurement also requires the use of cuffed ETT to minimise inspired tidal volume leakage in most cases.

Triggered modes are used in patients who are spontaneously breathing. The aim is to have the patient lightly sedated, exercising the respiratory muscles and synchronising well with the ventilator. Appropriate triggering, inspiratory time and cycling to expiration are all important aspects of establishing synchrony.[4]

PEEP of at least 5 cmH_2O is routinely used in all paediatric and neonatal patients, albeit empirically. Children expire to near their FRC so that any loss of muscle tone will lead to a greater likelihood of pulmonary atelectasis, hence a small amount of distending pressure is desirable.[70], [71] As in adults, PEEP is increased as needed for oxygenation. High-pressure recruitment manoeuvres are avoided. PEEP is unlikely to be increased beyond 15 cmH_2O. Adult strategies advocate higher PEEP but neonatal and paediatric preference is usually to change to HFOV if adequate gas exchange cannot be maintained.

Liberation from mechanical ventilation is not limited to the weaning of the mechanical ventilatory parameters but encompasses multidisciplinary care. Whilst there have been benefits shown in some units this has not translated into significant clinical improvements in metrics such as mortality, length of mechanical ventilation and duration of admission when studied widely.[72,73]

High-Frequency Oscillator Ventilation

HFOV has been instrumental in the care of infants with severe respiratory failure from any number of causes.[74,75] Unlike adult intensive care[76] it remains an important modality for the treatment of pARDs. In essence, it is a set pressure, the mean airway pressure (MAP), with an oscillation of 6–12 Hz around this. Oscillations are sinusoidal with negative and positive deflections. MAP, frequency and amplitude of the ventilator waveform influence oxygen and carbon dioxide clearance in discrete but not entirely independent ways. MAP and inspired oxygen are the primary determinants of oxygenation. Frequency and amplitude are the primary determinants of carbon dioxide clearance. Alveolar ventilation is said to occur by convective and diffusional mechanisms. These include bulk gas movement, laminar and turbulent flow, Pendeluft ventilation (between alveoli), collateral ventilation by alveolar channels and Taylor dispersion.

Children ventilated with HFOV are often heavily sedated and have neuromuscular-blocking agents administered. However, depending on pathology and stability, they may be allowed to breathe on top of the oscillations of the ventilator. These spontaneous breaths are not supported, so the clinician must ensure that the bias flow through the circuit is sufficient to maintain the MAP and allow for this tidal ventilation by the patient. For neonates and small infants, this tidal volume is negligible compared with the bias flow. For older children, this can be challenging and difficult to achieve. Secretion clearance and humidification of gases can be challenging. High bias flow results in inadequate humidification of inspired gases. Condensation of humidification, ‘Rain-out’, within circuits is frequently an issue. Weaning can be achieved whilst on HFOV, but most units convert to conventional ventilation for weaning, especially in older children who need larger tidal volumes.

Extracorporeal Life Support

Extracorporeal life support (ECLS) is considered when ventilation strategies have failed. Dramatic improvements in ECLS were promoted by improvements in cardiopulmonary bypass technology, increasing use of ECLS generally and developments in congenital heart surgery. [77]

Neonates across the spectrum of the ELSO registry have the greatest survival rates, particularly neonates supported with meconium aspiration syndrome. [78]

ECLS for neonates, infants and small children is typically achieved by surgical cannulation in the neck with the right common carotid and right internal jugular vein being accessed. Femoral vessels may also be used in older children, but they are unable to provide adequate flow in babies and infants. Veno-arterial (VA) ECLS is common, but veno-venous (VV) ECLS via a double-lumen catheter or two-vein cannulation is becoming more common for pure respiratory support. Failing the effectiveness of these a surgical trans-sternal central canulation strategy can be used.

Paediatric fluid and electrolyte therapy

Sophie Skellett

Fluid and electrolyte therapy is an important aspect of the care of critically ill children. In some regards, children and infants differ from adults, but many of the debates regarding fluid therapy are similar.

Intravenous (IV) fluid therapy may be required to correct or maintain fluid and electrolyte balance for normal physiological function in acutely unwell children for several reasons. It is important to distinguish these reasons as the treatments differ, and conditions may co-exist:

- **IV fluid resuscitation** : to rapidly expand effective circulating volume in the intravascular space to restore blood flow to the vital organs.
- **IV maintenance fluids** : if unable to tolerate enteral feeds or fluids to meet their fluid needs.
- **IV fluid replacement** : to compensate for ongoing losses (e.g., vomiting and diarrhoea).

Children and Infants Are Different

They require proportionally greater volumes of water for their weight than adults to maintain their fluid equilibrium and are more susceptible to fluid depletion and fluid losses. The reasons include:

- High total body water (TBW) content: TBW in preterm neonates can be as high as 80%; infants 70%; children 65%; adults 60%. As the child grows the intracellular space increases and the extracellular space reduces.
- Higher surface area to body mass index results in higher transepidermal losses, particularly in neonates, and this also increases susceptibility to changes in environmental temperatures.
- Higher metabolic and respiratory rates: increased use for growth (dramatic in the first year particularly) and increased water loss from lungs.
- Immature renal function: low glomerular filtration rate (GFR) at birth (25% of adult values) gradually increasing over the first year and immature renal concentrating function in neonates and infants, which can result in water loss in urine even in the face of dehydration.
- Dependency on caregivers for fluids and food and an inability to communicate needs. To compound this, dehydration in this group is not always easy to identify. [1]

As a result, great care and attention must be paid to IV fluid therapies as the morbidity and mortality can be significant. Children and infants, unlike adults, are prescribed IV fluids based on their body weight. Additionally, children and infants with hyponatraemia are at greater risk of developing cerebral oedema and neurological complications compared to adults. [2]

Fluids in Resuscitation

Evidence for size and composition of the fluid bolus used for resuscitation in the setting of circulatory failure from a variety of causes is limited in paediatrics.

Bolus Size

Prior to 2021 the accepted practice for the management of circulatory failure and shock was prompt, and early resuscitation with IV fluid boluses each of 20 mL/kg delivered over 5–10 minutes and repeated until circulatory status was stable and vital organ perfusion restored. Although this was largely based on observational studies, [3] the practice occurred alongside a huge reduction in paediatric mortality from sepsis in the developed world. In 2010 a large randomised controlled trial (RCT) of fluid bolus therapy 20–40 mL/kg of either 0.9% saline or 5% albumin solution versus maintenance fluids only in East African children with severe febrile illness was published, which showed that bolus therapy was associated with significantly higher mortality. [4] This study was set in a resource-poor setting with no intensive care back-up and fewer than 3% of patients met the World Health Organisation (WHO) criteria for the diagnosis of shock, hence it is probable that some patients treated with fluids did not require them. [5] This trial therefore does not offer conclusive evidence that fluid bolus therapy is unsafe. Nevertheless, it caused those who look after critically ill children to pause and subsequently several international guidelines changed recommendations for fluid bolus size.

The aim of IV fluid bolus therapy is to treat shock and restore circulating volume whilst avoiding fluid overload (FO). It is important therefore that after giving an IV fluid bolus there is careful re-assessment of the child's clinical status. This assessment should include the capillary refill time (CRT), blood pressure, peripheral and central pulse volume, heart rate, liver edge (and any change in this after giving a bolus), presence or absence of basal lung crepitations (the latter two may indicate FO), urine output and the level of consciousness of the child (blood lactate may also be helpful). If further fluid boluses are indicated, they should not be withheld but careful re-assessment should follow each one. Current recommendations for IV fluid bolus size vary: 10 mL/kg (WHO recommendation, EPALS [6]); 10–20 mL/kg (Surviving Sepsis Campaign Guidelines for Children 2020 [7]); 20 mL/kg (PALS [8]). IV or intraosseous (IO) fluid boluses are delivered over 5–10 minutes. In the case of sepsis, early use of inotropes or vasopressors should be considered; that is after IV/IO fluid boluses of 40–60 mL/kg in total have been given within the first hour of resuscitation, as this represents more than half the circulating volume of the child.

Targeted Fluid Bolus Therapy

Early Goal Directed Therapy (EGDT) [9] was used in the treatment of septic shock in children in the early 2000s in the developing world. This involved achieving several target parameters aimed at improving oxygen delivery to the tissues during resuscitation including fluid bolus therapy to a targeted central venous pressure (CVP) value. However, subsequent trials [10–12] in adults with sepsis found that the EGDT group received increased use of IV fluid, vasopressors and inotropes with similar mortality outcomes. It seems likely that CVP-directed IV fluid bolus administration is not a useful practice and more conservative fluid strategies may be indicated. In the past 15 years mortality from septic shock has reduced markedly in adults and children and there have been changes in many aspects of ICU practice; combined, these may have made any minor benefits derived from EGDT, at the time of the first trial, less significant.

In children the need for fluid administration in sepsis should be guided by frequent re-assessment of clinical markers of cardiac output, serial blood lactate measurement and advanced monitoring, when available (cardiac output/cardiac index and systemic vascular resistance measurements using invasive arterial blood pressure monitoring with pulse contour analysis or ultrasound Doppler of the ascending or descending thoracic aorta (suprasternal or oesophageal Doppler) and/or cardiac ultrasound/echocardiography, or central venous oxygen saturation ($ScvO_2$)).

Fluid Overload

The physiological rationale for fluid bolus therapy is in increasing stroke volume and hence cardiac output. If an increase in cardiac output is not achieved by volume expansion, the potential harm from fluid therapy outweighs the benefits. The ability of the clinician to estimate fluid responsiveness or indeed cardiac output [13] remains poor; hence frequent re-assessment is indicated.

The morbidity and mortality resulting from fluid administration during resuscitation and intensive care admission are largely related to FO, though the fluid composition may also influence this. Is it just that sicker children need more fluid resuscitation? One study in over 600 children looked at oxygenation, length of ventilation and outcome in relation to the percentage of fluid overload (FO) at 48 hours whilst controlling for severity of illness. [14] It found that the percentage of FO at 48 hours correlated to length of ventilation and oxygenation index but not mortality; similar results were seen in another smaller paediatric study. [15] Other studies in both adults and paediatrics have suggested a deleterious effect on renal function and mortality associated with FO though the evidence for this is not yet conclusive. [16–19] It would appear that positive fluid balance after restoration of effective circulating volume may negatively affect organ function in children in paediatric intensive care (PICU) and should be avoided and treated promptly. Critically ill children are particularly susceptible to FO because of the high incidence of inappropriate anti-diuretic hormone (ADH) secretion (discussed later).

There are certain clinical situations where a smaller fluid bolus size should be considered.

Diabetic Ketoacidosis

Mortality from diabetic ketoacidosis (DKA) is low in developed countries but can be caused by: cerebral oedema (25% mortality) which is unpredictable and occurs more frequently in younger children and newly diagnosed diabetes (aetiology is poorly understood but large fluid shifts should be avoided); inadequate resuscitation; hypokalaemia; aspiration pneumonia. It is uncommon for a child with DKA to present with shock; they will be dehydrated but these fluid losses can be more slowly replaced. However, if the child presents with severe DKA (defined as pH <7.1 or bicarbonate < 5 mmol/L with 10% dehydration) with shock they may require cautious administration of up to three or four 10 mL/kg fluid boluses [20] (with careful re-assessment after each one) to restore effective circulating volume (thereafter vasoactive medications may be required). Isotonic crystalloid fluids should be used in the form of 0.9% saline which in this clinical situation may be preferred over a balanced crystalloid solution because of the higher sodium content (desirable in the face of potential cerebral oedema). Some studies suggest that rapid, large-volume fluid administration in DKA is associated with a greater risk of cerebral oedema. [21]

Cardiac Failure

Assessing volume status in infants and children presenting with heart failure is difficult. Lesions leading to volume overload and congestive heart failure (e.g. ventricular septal defect presenting at 6 weeks of age) benefit from diuresis. However, a history of poor feeding, weight loss and excess energy expenditure may result in a volume deplete state, in which case the clinician may trial fluid resuscitation. In this setting, it can be difficult to determine if fluid may improve the infant's condition or cause worsening heart failure. If the clinician decides to try IV fluid therapy, this should be restricted to a 5 mL/kg bolus of isotonic crystalloid fluid with careful re-assessment to determine if the condition is improved or made worse by fluid therapy.

Trauma

Recent studies in mostly adult trauma patients indicate that excessive fluid and blood administration causes excessive morbidity and mortality in the least severely injured patients. [22] The WHO recommendation for cautious fluid and blood therapy with bolus sizes of 10 mL/kg with careful re-assessment after each bolus appears sensible and may prevent early clot destabilisation. When giving blood, bedside haematocrit evaluations may help guide further therapy. Most traumatic injuries in children are head injuries which may result in traumatic brain injury (TBI). TBI outcome can be positively influenced by maintaining good blood pressure and oxygenation. Fluid bolus therapy and inotropes can be used to help maintain good blood pressure, but FO may adversely affect cerebral oedema. If an isotonic crystalloid fluid bolus is used in the setting of head trauma, 0.9% saline may be preferred because of the higher sodium content compared to balanced crystalloid solutions.

Bolus Composition

Fluid boluses should be composed of isotonic crystalloid fluids and the most frequently used is 0.9% saline (Na^+ 154 mmol/L, Cl^- 154 mmol/L). Hypotonic fluid boluses cause hyponatraemia resulting in dangerous fluid shifts, which potentially cause cerebral oedema and seizures as water moves intracellularly. Additionally, isotonic fluids expand the intravascular compartment more effectively than hypotonic fluids.[23] Starch or gelatine-containing fluids are not used for fluid bolus therapy in children due to their detrimental effects (large synthetic molecules interfere with coagulation and renal function).

Glucose-Containing Fluids

Glucose-containing fluids are quickly metabolised to water; hence, the glucose content should not be taken into consideration when calculating tonicity of an IV fluid to be given as they are effectively hypotonic in vivo. Glucose-containing fluids should only be used to correct hypoglycaemia because hyperglycaemia is associated with poor outcomes in critically ill children, particularly those with central nervous system (CNS) pathology and trauma. Hypoglycaemia is also associated with poor outcomes in the acutely unwell child so must be sought and corrected if found. If a child or infant has a blood glucose <3 mmol/L then 2–5 mL/kg 10% dextrose (recommendations differ: EPALS 2 mL/kg, WHO 5 mL/kg) should be given as a bolus and the blood glucose rechecked within 5 minutes; if the hypoglycaemia recurs, repeat the bolus and ensure maintenance fluids with glucose are started to maintain normoglycaemia. Tight control of glycaemia (maintaining blood glucose 4–7 mmol) in critically ill children is of no benefit and may lead to increased numbers of children suffering hypoglycaemia from the higher doses of insulin administered.[24]

Colloid and Crystalloid Debate

Saline at 0.9% is an isotonic, cheap and infection-free crystalloid. Colloids are indicated for fluid therapy in some circumstances, such as blood to replace blood loss in haemorrhage, but routine use for volume expansion is declining as studies fail to show superiority over crystalloids with respect to hemodynamic effects[25] and in some situations indicate they may cause harm.[26] The SAFE study, compared human albumin solution (HAS) 4.5% with 0.9% saline in adults for fluid resuscitation and found no difference in mortality between the two groups.[27] Once commonly used in paediatric practice, the use of 4.5% HAS is now decreasing; it is expensive, carries an infection risk and because albumin is in suspension in 0.9% saline it carries the same risk of causing hyperchloraemic acidosis.

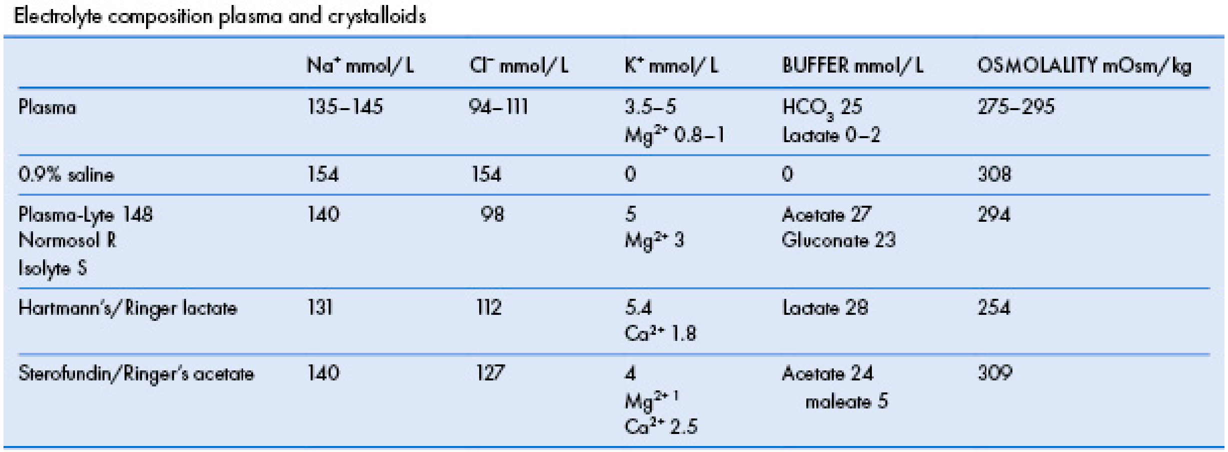
Hyperchloraemic Acidosis

Normal saline (0.9% saline) bolus therapy is associated with the development of hyperchloraemic acidosis as comparatively it contains a much higher concentration of chloride (Cl^-) ions than is present in the plasma, and it has a pH of 5.5, hence it is not 'normal'. It also has a slightly higher concentration of sodium (Na^+) ions than in the plasma, but this is a much smaller difference. Normal plasma concentration of sodium ions is 140 mmol/L, normal plasma concentration of chloride ions is 100 mmol/L. After several large fluid boluses have been given metabolic acidosis ensues from chloride excess. Calculating the anion gap (AG) shows a normal result in the face of acidosis:

$$\begin{gathered}\mathrm{AG} = (\mathrm{Na} + \mathrm{K}) - (\mathrm{Cl} + \mathrm{HCO_3})\ \text{range } 8-12\ \text{mmol/L} \\ \left(\text{where } \mathrm{HCO_3^-} = \text{bicarbonate}\right)\end{gathered}$$

For many years this acidosis was not thought to be significant, but some studies have suggested that this may not be the case and that either the acidosis and/or the chloride load may have deleterious effects on coagulation and kidney function (renal vasoconstriction and GFR reduction).[28, 29] This suggests that perhaps a more 'physiological' solution should be considered. 'Physiological solutions' or 'balanced solutions' contain lower concentrations of chloride, and a buffer is provided so that the solutions are electroneutral. Buffers used in some of these solutions include acetate, lactate, gluconate and maleate (Table 93.1). Lactate is metabolised to bicarbonate, as is acetate but gluconate is largely excreted in the urine unchanged. One large retrospective study in children compared the use of balanced solutions and unbalanced solutions (0.9% saline) for resuscitation in over 30,000 patients with sepsis and found decreased incidence of acute kidney injury and a suggestion of improved survival in the much smaller group receiving balanced fluid resuscitation.[30] Adult trials have also found benefits[31], [32] though this is not replicated in all studies.[33] Paediatric studies looking at the outcome between balanced and unbalanced solutions in children is an interesting area for further development.[34] Some examples of balanced solutions are shown in Table 93.1 .

Table 93.1



Electrolyte composition plasma and crystalloids

	Na^+ mmol/L	Cl^- mmol/L	K^+ mmol/L	BUFFER mmol/L	OSMOLALITY mOsm/kg
Plasma	135–145	94–111	3.5–5 Mg^{2+} 0.8–1	HCO_3 25 Lactate 0–2	275–295
0.9% saline	154	154	0	0	308

Plasma-Lyte 148 and Hartmann's/Ringer lactate solution manufactured by Baxter Healthcare Corporation; Normosol R manufactured by Hospira; Sterofundin/Ringer's acetate and Isolyte manufactured by B Braun.

Maintenance Fluids

Children and infants unable to tolerate enteral feeds and fluids may require IV fluid maintenance. The aim is to provide fluid and electrolytes to maintain extracellular volume and hence tissue perfusion; it is calculated based on 'expected' daily fluid and electrolyte losses. However, the most effective means of calculating routine maintenance requirements for infants and children, particularly whether weight or body surface area is the more appropriate, and what the composition of maintenance fluids should be remains controversial.

The most used formulae for calculating IV fluid requirements are those developed by Holliday and Segar in 1957, but there remains no consensus for their use. [35] The caloric expenditure for the average active child was calculated based on body weight and for every 100 calories burned there was approximately 100 mL of water lost. This resulted in the maintenance fluid requirements for every 24 hours calculated as follows, giving the so-called 4-2-1 rule for calculating maintenance:

4 mL/kg/h for the first 10 kg body weight of the child or infant, plus
2 mL/kg/h for every kilogram between 11 and 20 kg body weight, plus
1 mL/kg/h for every kilogram above 20 kg body weight (maximum 100 ml/h)

Daily electrolyte requirements were also calculated based on dietary intake as follows:

Na^+ 3 mmol per 100 calories; K^+ 2 mmol per 100 calories; Cl^- 2 mmol per 100 calories

For many years after this formula was published, fluids subsequently chosen for ‘standard’ maintenance for children and infants were often 0.45% saline with dextrose or more hypotonic fluids (0.18% saline/4% dextrose) at volumes far higher than needed; this practice resulted in an increased risk for the development of hyponatraemia and FO.

These ‘standard’ calculated volumes do not apply to the entire hospitalised paediatric population. This is particularly true for children in PICU who are inactive and frequently have conditions that impair normal water and electrolyte handling (for example the syndrome of inappropriate anti-diuretic hormone, see later) and as a result require far less water.

Anti-diuretic Hormone

Sodium and water regulation is usually controlled by a combination of interactions of arginine vasopressin (also known as anti-diuretic hormone or ADH), the renin–angiotensin–aldosterone axis and natriuretic peptides. Normally when plasma osmolality increases, ADH is released from the posterior pituitary in response to the activation of osmoreceptors in the hypothalamus and baroreceptors in the carotid sinus, aortic arch and left atrium. ADH acts on the kidney at the collecting ducts making them more permeable to water (by insertion of aquaporin channels) and by increasing medullary tonicity resulting in the conservation of water. [23] When patients are unable to drink in response to thirst then ADH will be the main determinant of plasma osmolality. If disease states or drugs affect the release or action of ADH then sodium/water homeostasis will be disturbed. In critically ill children and infants, there are several triggers that can cause ADH to be released without the usual trigger of an increase in plasma osmolality or volume depletion; this is called the syndrome of inappropriate ADH (SIADH). The triggers include:

- **CNS disease** : meningitis, encephalitis, head injury, space-occupying lesions
- **Pulmonary disease** : mechanical ventilation, pneumonia, asthma, hypoxaemia, hypercapnia and bronchiolitis
- **Drugs** : opiates, barbiturates, valproate, ciprofloxacin and chemotherapy
- **Surgery** : postoperative states
- **Other** : Pain, nausea, vomiting, hypoglycaemia, inflammation and cancer

The result is retention of excess free water making the patient susceptible to the development of hyponatraemia (this was not a recognised entity in the 1950s when the Holliday-Segar formulae were devised). The diagnosis of SIADH can be made by the patient fulfilling the following criteria:

- Na+ < 135 mmol/L, serum osmolality < 275 mOsm/kg, clinical state of euvolaemia, urine osmolality > 100 mOsm/kg, urinary sodium excretion > 40 mmol/L

This will usually occur in the clinical setting of a positive fluid balance. SIADH is managed with fluid restriction to half to two-thirds of daily maintenance, use of isotonic IV maintenance fluids (if on IV fluids) with regular monitoring of paired serum and urine sodium and osmolality levels, and daily patient fluid balance and weight measurements.

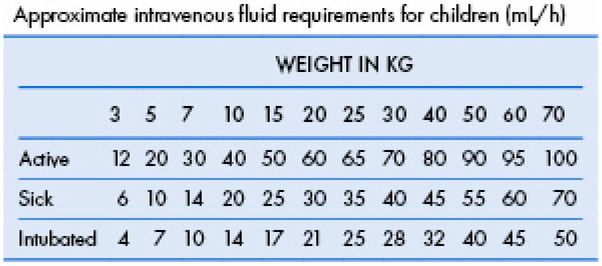
Volume adjustments to ‘standard’ maintenance for children and infants in intensive care should be made not only in the setting of SIADH but for a variety of other reasons, including reduced metabolic rate when sedation and muscle relaxants are used, reduced water losses if ventilated with humidified inspired gas and maintenance of body temperature. [36–41] Table 93.2 outlines the adjustments that should be made in each setting and Tables 93.3 and 93.4 give a guide to maintenance fluid volumes in the active, sick and sick plus intubated ventilated patient.

Table 93.2

ADH , Anti-diuretic hormone; *IPPV,* intermittent positive-pressure ventilation.

Table 93.3

Table 93.4



Approximate intravenous fluid requirements for children (mL/h)

	WEIGHT IN KG											
	3	5	7	10	15	20	25	30	40	50	60	70
Active	12	20	30	40	50	60	65	70	80	90	95	100
Sick	6	10	14	20	25	30	35	40	45	55	60	70
Intubated	4	7	10	14	17	21	25	28	32	40	45	50

Worked example : **15 kg child with a head injury**

Standard maintenance = 4 mL/kg/h (first 10 kg weight) + 2 mL/kg/h for (each kg between 10 and 20 kg weight) = $(4\times10)+(5\times2)=$ **50 mL/h** maintenance fluid [35]

- Adjust for SIADH by (× 0.7 [37])
- Adjust for muscle relaxant decrease in metabolic rate (× 0.7 [35])
- Adjust for ventilation with humidified gas (× 0.75 [36])
- Adjust for maintenance of body temperature 36° (– 12%)

Now total maintenance fluids $= (50 \times 0.7 \times 0.7 \times 0.75) - 12\% =$ **16 mL/h**

The variety in fluid needs of critically ill patients requires that each child and infant has a tailored approach to their IV fluid prescriptions daily, and emphasises the vital importance of close monitoring of the fluid balance in the ICU with daily weights when possible.

Composition of Maintenance Fluids

A meta-analysis of 17 RCTs, involving 3356 paediatric patients, compared the use of hypotonic and isotonic maintenance fluids and showed that use of isotonic solutions did not predispose to hypernatraemia and significantly reduced the risk of hyponatraemia compared with hypotonic fluids, with an odds ratio of 0.41. [42-46] Hypernatraemia does not occur as a result of the use of 0.9% saline in patients unless there is a renal concentrating defect or a large extra renal free water losses because the kidney is capable of excreting hypertonic urine. [23] Isotonic fluids are therefore the preferred choice for IV maintenance fluids when the enteral route cannot be used.

Isotonic fluids are those with a sodium concentration in the range similar to that found in plasma, 131–154 mmol/L (Table 93.1). 0.9% saline is ‘unbalanced’ because it contains chloride ions in a much higher concentration to that found in plasma (see above). Balanced crystalloid solutions (e.g., Hartmann’s solution, Ringer lactate and Plasma-Lyte) have a sodium, potassium and chloride content closer to that of extracellular fluid and, when given intravenously, have fewer adverse effects on acid-base balance.

In a meta-analysis of 5 studies, including 283 patients, balanced isotonic maintenance fluids were associated with a small but significant reduction in the length of stay for critically unwell children (mean difference: −0.20 days; 95% CI [−0.33; −0.08], $P = .001$).[42]

Dextrose can be added to maintenance fluids for children and infants to give sufficient glucose to prevent hypoglycaemia and limit tissue catabolism (in the short term).

In general, it is recommended that children and infants have balanced isotonic crystalloid IV fluid maintenance at least as initial therapy (0.9% saline is an acceptable alternative) and then at least daily plasma electrolyte measurements with fluid balance measurements and weight measurements (where possible) to tailor their ongoing IV fluid needs. Importantly, children and infants should be fed enterally whenever possible and as soon as possible, obviating the need for IV maintenance fluid therapy as this provides both gut protection and nutrition.

Replacement Fluids

Children may also need IV fluids to account for losses beyond the usual losses in urine, stool and sweat; the aim is to replace any depleted fluids and restore electrolyte imbalances. The speed of fluid deficit replacement is determined by the child's clinical condition; in most cases of gastroenteritis this may be achieved in 24 hours (and preferably by the enteral route) but for children with DKA, hypernatraemia and or CNS pathology deficit, fluids should be replaced more slowly over 48 hours. Do not forget to check the blood glucose of any child presenting with dehydration, particularly in the setting of altered mentation.

Weight loss is the best method of assessing the degree of dehydration[1] (though pre-illness weights may not be available for comparison).[46] Clinical assessment of dehydration is less reliable,[1] but some of the more useful clinical signs are: decreased peripheral perfusion, as demonstrated by prolonged CRT; deep breathing; decreased skin turgor.

Because of the difficulty in determining the degree of dehydration, several other methods of assessing this have been developed. These include a number of clinical scores, such as the clinical dehydration scale and Gorelick scores[47,48]; bedside ultrasound measurement of the ratio of aortic diameter to inferior vena cava diameter (IVC)[49,50] or degree of inspiratory IVC collapse [51] ; urinary ketone measurement [52] ; and capillary digital videography. [53] A meta-analysis [54] looking at the usefulness of the various techniques concluded that clinical dehydration scores were more accurate than unstructured clinical examination, though still not optimally accurate. Current evidence does not support the use of ultrasound or urinalysis to determine the severity of dehydration in children; there was insufficient evidence to assess the usefulness of capillary digital videography.

Dehydration can be classified as either mild (< 5% weight loss), mild to moderate (5–10%) or severe (>10%). IV fluid therapy is usually given to treat cases of severe dehydration, whilst for mild to moderate dehydration oral/enteral rehydration is preferred.

Mild to Moderate dehydration

Signs and symptoms : sunken fontanelle, fewer than six wet nappies over 24 hours, dry mouth, thirst, normal to mildly prolonged CRT, normal to slight increase in respiratory rate, mildly decreased tissue turgor.

Severe

Signs and symptoms : irritable, lethargic, reduced urine output, cold hands and feet, prolonged CRT, signs of shock, decreased skin turgor (difficult to assess in obese or malnourished children), altered mental status, tachypnoea and hyperpnoea, tachycardia and/or bradycardia.

A child’s water deficit can be calculated following an estimation of the degree of dehydration expressed as percentage of body weight. The deficit is usually replaced over 48 hours, but this should be adjusted according to the child’s clinical condition and plasma electrolyte measurements as rehydration proceeds.

$$\text{Deficit}\ (\text{mL}) = \text{weight}\ (\text{kg}) \times \%\ \text{dehydration} \times 10$$

Worked example : 10 kg child with 10% dehydration from diarrhoea

$$\text{Fluid deficit (ml)} = 10 \times 10 \times 10 = \mathbf{1000\ ml}$$

The child received two 10 mL/kg bolus of 0.9% saline (200 mL) to restore effective circulating volume leaving an 800 mL deficit to be **replaced over 48 hours** = **16.5 mL/h**

Then add **the maintenance** requirement = 4 mL/kg/h for first 10 kg weight = **40 mL/h**

Then the child should be given: 40 + 16.5 mL/h = **56.5 mL/h for 48 hours.**

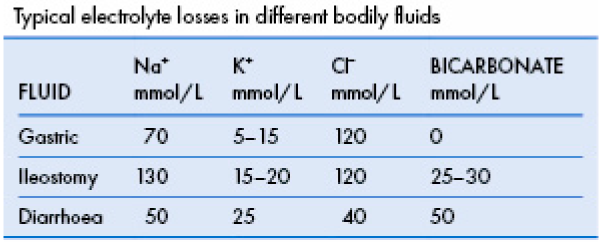
The more common causes of increased loss of fluid from the intravascular space in children and infants are outlined in Table 93.5 .

Table 93.5

CNS , Central nervous system; *DI* , diabetes insipidus; *DKA* , diabetic ketoacidosis; *GI* , gastrointestinal.

The replacement of ongoing fluid losses in the ICU depends on accurate measurements of all the losses (e.g. stoma, gastric, wound and chest drain losses and urine output) and fluid balance measurements together with serum electrolyte, blood gas and lactate analysis. Ongoing losses are best measured and if significant replaced either hourly or over each subsequent 4-hour period depending on the clinical setting. The type of fluid chosen will be dependent on the type of fluid loss. Table 93.6 indicates typical electrolyte losses in different bodily fluids.

Table 93.6



Typical electrolyte losses in different bodily fluids

FLUID	Na^+ mmol/L	K^+ mmol/L	Cl^- mmol/L	BICARBONATE mmol/L
Gastric	70	5–15	120	0
Ileostomy	130	15–20	120	25–30
Diarrhoea	50	25	40	50

A few conditions requiring special consideration with regard to fluid management in children and infants are outlined as follows:

1. In a child with oliguria following a severe ischaemic or hypoxic insult (such as birth asphyxia, drowning or cardiac arrest), it may be helpful to measure the urine sodium concentration to determine fluid therapy. [55] In oliguria due to acute tubular necrosis, where the restriction of fluid intake may be necessary, the urine sodium is usually more than 40 mmol/L. In oliguria due to hypovolaemia, the urine sodium is usually less than 20 mmol/L. Urinary sodium measurement is an unreliable guide to volume status if diuretics have been administered.
2. Conditions requiring increased free water to compensate for losses [23] are prematurity, burns, fever and diarrhoea.
3. Conditions requiring increased free water to compensate for renal concentrating defects [23] are nephrogenic diabetes insipidus (DI), sickle cell disease and renal dysplasia. In such circumstances, the administration of hypotonic fluids may be indicated.
4. Conditions requiring increased salt and water to compensate for solute diuresis [23] are polyuric phase of renal acute tubular necrosis, DKA and cerebral salt wasting.
5. Condition requiring salt and water restriction in the setting of polyuria [23] is renal failure.
6. Conditions requiring fluid restriction for oedematous states [23] are heart failure and nephrotic syndrome (isotonic fluids but small volumes).

Sodium

Sodium is the principal determinant of effective plasma osmolality as it is the main extracellular ion and cannot move freely into cells. Changes in serum sodium should be interpreted in conjunction with the child's hydration status as they are usually due to changes in body water rather than total body sodium.

In the first 1 or 2 days of life, small preterm babies often have poor urine output and high transcutaneous fluid losses. They are therefore prone to hypernatraemia and hyperkalaemia, and such infants should usually be given 10% dextrose without sodium or potassium. From 2 days of age, 2–4 mmol/kg/day of sodium and potassium will usually be sufficient, but much higher intakes of sodium are needed in some preterm neonates owing to their impaired renal conservation of sodium.

Causes of Hyponatraemia

- Associated with **HYPERVOLAEMIA** : IV fluid administration in excess of the child's needs; cirrhosis; heart failure; acute/chronic renal failure; nephrotic syndrome.
- Associated with **EUVOLAEMIA** : Administration of enteral hypotonic fluids (including dilute formula, oral rehydration solutions, excessive water intake); psychogenic polydipsia; increased ADH secretion, SIADH; Endocrine: hypothyroid, low cortisol); medications (including cyclophosphamide, vincristine, valproate, carbamazepine, vasopressin).
- Associated with **HYPOVOLAEMIA** : low body sodium due to diuretic therapy, cerebral salt wasting, excessive loss in sweat (cystic fibrosis), diarrhoea or vomiting; poor renal conservation of sodium, or a low sodium intake (e.g. breast milk); GI losses and rehydration with free water; hypoaldosteronism; metabolic alkalosis.

Hyponatraemia (defined as serum sodium (Na+) < 135 mmol/L) and associated fluid shifts can result in cerebral oedema causing neurological symptoms with serious neurological morbidity and even mortality. Children and infants, and those with hypoxaemia or CNS disease, are particularly at risk of hyponatraemic encephalopathy as there is reduced tolerance to brain oedema. Most children with Na >125 mmol/L are asymptomatic. Symptoms can appear at serum sodium levels of 120 to 125 mmol/L and include nausea, malaise and rarely seizures. If Na <120 mmol/L symptoms are more severe with headache, lethargy, obtundation and a higher likelihood of seizures. Hyponatraemia that develops more slowly (>24 hours) may have more subtle signs such as restlessness, weakness, tiredness or irritability (due to cerebral adaptation).

Rapid correction of hyponatraemia can result in central pontine myelinolysis (CPM) (also called osmotic demyelination syndrome) which can cause a range of severe, sometimes irreversible neurologic features (dysarthria, dysphagia, paralysis, confusion, obtundation and coma) that often present days after sodium correction; some patients may improve in the following weeks and months. Therefore hyponatraemia due to sodium deficit should usually be corrected slowly, raising the serum sodium by a maximum of 0.5 mmol/L/h. [56] The risk of CPM is thought to be related to the chronicity of hyponatraemia. However, if the child is seizing, urgent treatment to elevate the serum sodium may be required using 3% saline 4 mL/kg to raise the serum sodium by 3 mmol/L. [57] This can be repeated if the child is still seizing, targeting a level of 125 mmol/L after which the serum sodium level should be raised more slowly at a maximum of 0.5 mmol/L/h.

Hyponatraemia due to water excess rather than sodium deficiency, should be treated with a restriction of fluid intake or diuretics and or vasopressin V2 receptor antagonists in the non-urgent setting (depending on the diagnosis).

SIADH should be managed with fluid restriction to half to two-thirds of daily maintenance as previously described.

Causes of Hypernatraemia

- Associated with **HYPOVOLAEMIA** : diuretics (loop); post obstructive diuresis; acute and chronic renal disease; sweating, fistula, burns, diarrhoea, vomiting; DI (central, nephrogenic); osmotic diuresis (caused by glycosuria); inadequate fluid intake – inability to obtain water, including breastfed babies due to inadequate milk supply; high insensible losses.

- Associated with **EUVOLAEMIA/HYPERVOLAEMIA** : increased body sodium from the administration of large amounts of sodium (e.g. sodium bicarbonate, hypertonic saline, total parenteral nutrition [PN]) or salt poisoning.

Hypernatraemia is defined as serum sodium >145 mmol/L but can further be classified as: mild (146–149 mmol/L), moderate (150–169 mmol/L) and severe (≥170 mmol/L). Moderate to severe hypernatraemia can cause acute brain shrinkage with vascular rupture, haemorrhage, demyelination and permanent neurological injury; this occurs because fluid moves out of the brain causing structural changes with neuronal cell shrinkage. Infants and small children are more vulnerable to hypernatraemia due to greater insensible losses and inability to communicate their need for fluids or access fluids independently. Chronic hypernatraemia (>48 hours) is often well tolerated and asymptomatic due to cerebral compensation.

Hypernatraemia with dehydration shock should be treated with IV fluid bolus therapy and the water deficit should then be corrected very slowly using 0.9% saline, usually over 48 hours, so that the serum sodium falls no faster than 0.5 mmol/L/h, to prevent cerebral oedema. [58] If the decrease is too rapid (>0.5 mmol/L/h), stop or reduce the rate of fluids (hypertonic saline may be required to slow a rapid decrease in serum sodium levels) and monitor neurological status closely. If seizures occur, consider venous sinus thrombosis or cerebral infarction and consider imaging with a contrast CT scan. If salt ingestion causes severe acute hypernatraemia without dehydration, peritoneal dialysis or haemofiltration may be indicated.

Potassium

Potassium is predominantly an intracellular ion, so total body potassium is poorly represented by the serum concentration. The concentration of potassium in the serum depends on pH as well as the total body potassium (which is usually about 50 mmol/kg). A child may have hypokalaemia [59] without a deficit of total body potassium in the presence of alkalosis and, conversely, there may be a large total body deficit of potassium without hypokalaemia in the presence of acidosis. Potassium should be replaced in PICU if serum levels are as follows:

- 3 mmol/L in general PICU patients
- 4 mmol/L in post op cardiac patients
- 4.5 mmol/L for those at risk of arrhythmias (VT, JET)

All patients with volume depletion will have a potassium deficit (though not usually clinically significant) but if not corrected along with the volume replacement then significant hypokalaemia may develop. [23] Commonly, potassium is not added to replacement fluid until an adequate urine output is obtained. Potassium can be infused into a peripheral vein usually at concentrations up to 20 mmol/L. Higher concentrations must only be given centrally at a rate of no more than 0.3 mmol/kg/h, and this should be accompanied by cardiac monitoring. Hypokalaemia in PICU is common due to the use of loop diuretics; to minimise this, use a potassium-sparing diuretic alongside. If the child is tolerating > 50% enteral feeds, then enteral replacement of potassium is the preferred choice.

Calcium, Magnesium and Phosphate

Children with hypocalcaemia in PICUs have mortality rates higher than those of children with normal calcium levels. [60] Hypocalcaemia is defined as total serum calcium < 2.1 mmol/L. Symptoms occur when the ionised calcium level falls below 0.8–0.9 mmol/L. Hypocalcaemia in children occurs in:

- Sick neonates in the first 2 days of life and in infants of diabetic mothers
- Exchange transfusion with citrated blood (a temporary effect) and alkalosis

- Magnesium deficiency, loop diuretics, renal insufficiency, pancreatitis, sepsis
- Infants fed cow's milk (high phosphate content), vitamin D deficiency, hypoparathyroidism, Di George syndrome (22q11 deletion syndrome)
- Hyperphosphataemia (causes hypocalcaemia via binding) caused in the PICU setting by: renal disease and increased endogenous load (anoxia, rhabdomyolysis and chemotherapy).

Hypocalcaemia and hypomagnesaemia cause jitters, tetany, cardiac arrhythmias, laryngospasm and convulsions. Severe hypomagnesaemia (0.46 mmol/L) causes hypocalcaemia by impairing the secretion and action of parathyroid hormone (PTH). The doses of calcium and magnesium are given in Table 93.4 . The normal IV maintenance requirements in infants are 1 mmol/kg/day of calcium and 0.3 mmol/kg/day of magnesium.

Oedema

Oedema is common in children in PICUs. It may be due to:

- Fluid overload (often in combination with SIADH)
- Capillary leak (secondary to hypoxia, ischaemia, acidosis or sepsis), hypoalbuminaemia
- Heart failure, renal failure.

Children with fluid overload, oedema and high levels of ADH will have a low serum osmolality (with hyponatraemia) and a urine osmolality greater than 100 mOsm/kg; the appropriate treatment is fluid restriction. Conversely, in children with oedema due to capillary leak, fluid restriction and attempts to remove water (diuretics, dialysis) are unlikely to reduce the oedema, and often cause hypovolaemia; in fact, large amounts of fluid (e.g. blood and normal saline) may be needed to preserve the intravascular volume in these children – the oedema will resolve only when the capillary damage resolves.

Feeding and Parenteral Nutrition

Although IV maintenance fluids may contain glucose, they offer a very poor source of long-term nutrition, particularly for infants and younger children. A solution of 5% dextrose with sodium and potassium chloride provides maintenance amounts of water, sodium, potassium and chloride, but few calories and no protein, fat, trace elements or vitamins.

For example, 100 mL/kg/day of 5% dextrose provides 17 kcal/kg/day (70 kJ/kg/day), which is less than 20% of the requirement of a normal infant.

Therefore if IV maintenance fluids are used for more than a few days, a pronounced macronutrient deficit will develop, which predisposes the child to an increased infection rate, poor wound healing, muscle weakness (which may prolong mechanical ventilation) and subsequently delayed recovery with prolonged ICU stay. To prevent this, enteral feeding or nutrition (EN), generally via a nasogastric tube, should be instituted within the first 24 hours of ICU admission (ideally within 6 hours) as recommended in international guidelines. [61] EN is superior to PN as it helps maintain gut structure and function and should be increased in a stepwise fashion using a feeding protocol or guideline, (particularly when there is poor feeding tolerance). Depending on the case mix in PICU most children absorb adequate amounts of food from the gut; studies show that if 66% of nutrient targets are met with enteral feeds for children receiving mechanical ventilation they have a better outcome. [62] Post-pyloric feeding can be considered for children where there is a high risk of aspiration, gastric feeding intolerance or those requiring frequent fasting for surgery or procedures, but gastric feeding is not inferior to post-pyloric feeding in the majority of critically ill children and is the recommended route for EN for children on PICU. [61]

If enteral feeding cannot be achieved and in the setting of poor gut function, PN should be considered. A dedicated central line is required for delivery of PN due to the high osmolality of the solutions and 5%–10% of patients receiving PN via a central line will have complications related to the central venous access (misplacement or migration of the line, sepsis, thrombosis). Other complications include: glucose abnormalities (hypo- and hyperglycaemia); liver dysfunction, hepatomegaly, hyperammonaemia (particularly small infants); volume overload; electrolyte abnormalities; reactions to lipid emulsions; hyperlipidaemia; metabolic bone disease (usually after long-term PN).

The timing of administration of PN in critically ill children was studied in the PEPaNIC trial.[63] This large paediatric RCT ($n \geq 1400$ children) randomised critically ill children in the PICU to early (within 24 hours) or late (starting day 8 of admission) PN. Mortality was similar in the two groups, but the use of late PN resulted in clinically superior outcomes including fewer infections, shorter lengths of ventilation and shorter hospital stays (mirroring results in adult studies).[64] The explanation of these results is most likely multifactorial, but it should be noted that the actual caloric needs of the critically ill child are difficult to accurately estimate,[65] and the early PN group may have been overfed and/or this may reflect the risks associated with PN and the central catheter needed to deliver it.

Acknowledgements

I would like to acknowledge Professor Frank Shann, Professor of Children's Critical Care Medicine, Royal Children's Hospital, Melbourne, Australia, as the previous author and I have used much of his invaluable material; and Dr Peter Sidgwick, Consultant Paediatric Intensive Care, Great Ormond Street Hospital, London, United Kingdom, for reviewing my work and keeping me on track.

Sedation and analgesia in children

Andy Petros

An online survey of 357 European paediatric intensive care units (PICU), (response rate 60%) revealed widely different practices in providing analgesia and sedation including choice of agents, doses and assessment tools. First choice for analgosedation was fentanyl (51%) in combination with midazolam (71%) with starting doses for fentanyl ranging from 0.1–5 mcg/kg/h and for midazolam 0.01–0.5 mg/kg/h. Assessment of pain (81%) and sedation (87%) was reported by most of the PICUs, using the face, legs, activity, cry, consolability (FLACC) scale (54%) and the COMFORT Behavioural scale (48%), respectively. [1]

Assessment of Depth of Sedation and Pain

There is no one perfect scoring system to assess the adequacy of sedation or pain relief in children. The wide age spectrum from preterm neonates to 16-year-old teenagers requires age-appropriate tools. Consequently, there are several validated tools to match the various age groups. These fall into two main categories: (1) those that assess and score behaviours considered typical of distress and (2) those that judge the level of consciousness. One example of the latter is the University of Michigan sedation scale (UMSS) which assesses levels of consciousness on a scale of 0–4 with 4 being unconscious. [2] Another frequently used scale is the state behavioural scale (SBS) specifically designed for and tested in young intubated and mechanically ventilated patients. [3] Perhaps the most commonly used tool for assessing distress in children is the COMFORT scale subsequently modified to the COMFORT behaviour scale (COMFORT-B).[4] Both have been validated for assessing pain and sedation in ventilated and spontaneously breathing 0–18 year olds. Neither SBS nor Comfort-B score can be used in patients receiving muscle relaxants.

The Richmond agitation-sedation scale (RASS) is a simple tool that is easy to use and includes both agitation and sedation. It correlated highly against the visual analogue scale of 10 round cartoon faces ranging from crying to smiling and allows the accurate assessment of awareness in both ventilated and spontaneously breathing patients and enables carers to titrate sedatives and assess for delirium in paediatrics.[5]

Assessing postoperative pain in pre-verbal children can also be difficult. The FLACC scale[6] and the multidimensional assessment of pain scale (MAPS)[7] are both useful tools. In preterm and term neonates the neonatal pain, agitation and sedation scale (N-PASS),[8] the premature infant pain profile (PIPP)[9] and cry, requires oxygen, increased vital signs, expression and sleeplessness (CRIES)[10] scales have all been used and are objective measures of pain in this group.

The bispectral index (BIS) is a numerical scale (from 0 to 100, with 100 indicating awake status) derived from a processed electroencephalogram (EEG) and correlates with the level of consciousness. It is commonly used in adult and paediatric anaesthesia but is also used in PICU and an index range of 40–60 is considered an adequate level of sedation.[11] The use of BIS in children has its limitations because the algorithms used to generate the index range are derived mostly from adult data. The BIS is also not reliable under the age of 6 months.[12] However, it can be useful in children receiving muscle relaxants in whom it is not possible to assess behavioural indicators by observing trends in the index. Vet et al.[13] in a systematic review identified 25 randomised controlled trials (RCTs) reporting optimal sedation levels, scoring systems and agents used in the PICU. The most frequently used paediatric sedation scores were COMFORT, COMFORT-B (11/25) and SBS. Six studies (23%) included in the review reported the use of BIS. In addition, Vet et al's systematic literature search of 25 studies evaluating sedation levels in 1163 children concluded that optimal sedation was achieved only 57.6%, undersedation in 10.6% and oversedation in 32% of the time. [13]

Achieving Adequate Sedation

Pain, discomfort, anxiety, loss of the sleep–wake cycle, withdrawal symptoms and delirium are the challenges in paediatric intensive care.

It is important to achieve optimal levels of sedation as oversedation leads to tolerance, dependency and withdrawal symptoms. Numerous attempts have been made at producing sedation guidelines for children to try and optimise sedation (Table 94.1) . However, because of the relative paucity of evidence available for the various agents used, there are no universally adopted guidelines. The Pediatric Cardiac Intensive Care Society 2014 consensus statement on the use of sedation, analgesia and muscle relaxants attempted to establish some guidelines. Perhaps not surprisingly it concluded that the management of the cardiac patient requires an individualised sedative and analgesic strategy that maintains haemodynamic stability. [14] In addition to trying to rationalise which agents to use attempts have been made to protocolise the delivery and weaning of sedation. In a general PICU environment, a nurse-led and goal-directed sedation protocol could not produce any significant advantages over physician-led management. [15] A Cochrane review of protocol-directed sedation in 2018 included four studies involving 3323 children and found that there was no clear evidence of a difference in length of stay, mortality, duration of ventilation and incidence of self-extubation. The authors conclude there was no evidence to support the use of protocol-directed sedation. [16] In practice, the common default position in the PICU is nurse-led adjustments according to their subjective assessment of the child.

Table 94.1

Guidelines for the route of administration, bolus and infusion doses of commonly used sedative and analgesic agents in children. (Modified from the British National Formulary for Children)

DRUG	ROUTE	DOSAGE
Diazepam	IV	Bolus: 0.2–0.4 mg/kg
		Infusion: NOT recommended
Midazolam	IV	Bolus: 0.1–0.2 mg/kg
		Infusion: 1–4 µg/kg/min
Lorazepam	IV	Bolus: 0.1 mg/kg
Chloral hydrate	Oral	30–50 mg/kg 6–8 hourly
Alimemazine	Oral	1–2 mg/kg 6 hourly
Ketamine	IV	Bolus: 1–2 mg/kg
		Infusion: 10–40 µg/kg/min
Clonidine	Oral	4 µg/kg
	IV	Infusion: 0.1–2 µg/kg/h
Dexmedetomidine	IV	Infusion: 0.7–1.4 µg/kg/h
Thiopentone		Bolus: 2–4 mg/kg
		Infusion: 1–5 mg/kg/h
Paracetamol	Oral	20–30 mg/kg stat then 15–20 mg/kg to a max of 60 mg/kg/day
	IV	Bolus: 7.5 mg/kg <10 kg
		15 mg/kg >10 kg

DRUG	ROUTE	DOSAGE
	Rectal	30–40 mg/kg stat then 15–20 mg/kg to a max of 60 mg/kg/day
Morphine	IV	Bolus: 0.1–0.2 mg/kg
		Infusion: 10–40 µg/kg/h
Fentanyl	IV	Bolus: 1–2 µg/kg
		Infusion: 1–6 µg/kg/h for children 0–1.5 µg/kg/h for neonate
Remifentanil	IV	Infusion: 3–80 µg/kg/h 1 month–12 years
		3–120 µg/kg/h 12–18 years

IV , Intravenous.

Rather than leaving adjustments to the subjective assessment of any one individual, interruption of the continuous infusion of sedation improved outcomes. [17] Sedation breaks are another attempt at avoiding oversedation and dependence. In an RCT of 128 adult ICU patients who had their sedative infusions interrupted until fully awake compared to interruption at the discretion of the clinician, there was a reduction in the duration of ventilation and length of stay in ICU. [17] In a paediatric population the complete interruption of infusions also significantly reduced the length of mechanical ventilation, the duration of ICU stay and the total dose of midazolam administered. [18]

Agents for Sedation

Sedative agents do not provide analgesia. Hence a combination of analgesics and sedatives is the standard approach to ensure the child is comfortable and tolerates mechanical ventilation. The most frequently used sedatives in PICU include benzodiazepines, ketamine, barbiturates and more recently dexmedetomidine. Enteral agents are also used and include chloral hydrate and alimemazine.

Benzodiazepines

Benzodiazepines are the agents of first choice to reduce anxiety in children. Their main sites of action are on gamma-aminobutyric acid ($GABA_A$) receptors in the limbic and reticular activating systems. Benzodiazepines have a large volume of distribution due to their lipid solubility and are metabolised in the liver, being oxidised to active metabolites or converted to glucuronides and excreted in the urine. The production of active metabolites and enterohepatic recirculation prolong their duration of action.

Midazolam

Midazolam is probably the most used benzodiazepine in the PICU and is the drug of choice in combination with morphine to provide sedation and analgesia.[19] A single dose has an onset of action within 1–5 minutes and can last 30–120 minutes. It is metabolised in the liver to the equally potent 1-hydroxymidazolam. The oral dose is 0.5 mg/kg and is often used for premedication. The standard intravenous sedative dose is 0.1–0.2 mg/kg. As an infusion (1–4 µg/kg/min) it is frequently used in combination with an opioid. In higher doses it can cause respiratory depression and particular care must be taken in children with compromised cardiac function where it can induce significant hypotension. Midazolam infusion is not commonly used in neonatal intensive care because of concerns over neurodevelopment and neurological damage.[20] In PICU it is increasingly being recognised that midazolam is a major cause of withdrawal and delirium post-ICU. The use of midazolam as a continuous infusion may soon become obsolete in the PICU.

Clonidine

Clonidine is an α_2-adrenoreceptor agonist with a half-life of 9–12 hours. It can be administered either entrally or intravenously. It can also be given via the transdermal route as a patch delivering 0.1 mg per day. However, this may be a rather inflexible method for the acute environment of intensive care. If given orally it is metabolised by the liver and excreted by the kidney with approximately 50% unchanged in urine. Clonidine has an important role in managing opioid withdrawal by ameliorating the symptoms.

Dexmedetomidine

Dexmedetomidine is a selective α_2 -agonist with similar pharmacological properties to clonidine, although it is about eight times more potent. It is metabolised in the liver with no active metabolites. [21] The use of dexmedetomidine is increasing in the PICU and is replacing midazolam as the sedative agent of first choice. Several studies in children have investigated the safety and efficacy of dexmedetomidine. A continuous infusion of 0.7 µg/kg/h without a loading dose was well tolerated with minimal effects on heart rate and blood pressure. [22] In a single centre retrospective report of 144 children with a median age of 34 months, dexmedetomidine 0.05–2.0 µg/kg/h was well tolerated, although withdrawal symptoms were reported as a problem. [23] It is attractive because of its short half-life of 2 hours and relative lack of respiratory depression, it allows fewer opioids to be used and shortens the duration of mechanical ventilation. Dexmedetomidine has been used in term and preterm neonates for up to 24 hours without serious side effects. [24]

In six tertiary PICUs in Australia and New Zealand, dexmedetomidine was used as the main sedative agent for the first 48 hours and produced light sedation with significantly reduced cumulative doses of midazolam. [25] A meta-analysis of seven studies involving 1188 children demonstrated a reduction in the length of ICU and hospital stay with the use of dexmedetomidine between propofol and dexmedetomidine sedation, though there was no difference in duration of ventilation or morality. [26] Both studies reported an incidence of bradycardia and hypotension. Bradycardia and hypotension are seen with dexmedetomidine and clonidine during continuous infusion.

The use of dexmedetomidine to modify the incidence of iatrogenic withdrawal syndrome (IWS) was attempted in 45 children 24 hours prior to starting to wean from opioid/benzodiazepine administration and for at least 5 days. This did not modify the prevalence of IWS. [27]

Ketamine

Ketamine is a non-competitive antagonist of the excitatory neurotransmitter *N*-methyl-d-aspartate (NMDA) receptor sites in the central nervous system (CNS). Its onset of action is about 2 minutes to achieve maximal effect after an intravenous dose of 1–2 mg/kg and can be longer when given intramuscularly. It has a duration of action of 10–20 minutes. Ketamine produces a dissociative anaesthetic state where the patient appears to be awake with eyes open but is anaesthetised and pain free.

Systemic effects include increased cerebral blood flow and intracranial pressure. Cardiovascular effects include an increase in cardiac output, pulmonary vascular resistance and systolic and diastolic pressures. It is metabolised in the liver and its metabolites are less potent.

Ketamine is very useful in paediatric practice for venous access or repeated minor surgical procedures. It also has a role in severe asthma as the agent of choice for intubation and continued sedation as opposed to morphine, which can release histamine. It also has bronchodilator properties. A continuous infusion of 10–40 μg/kg/min can be used. Ketamine increases secretions of saliva and can cause unpleasant hallucinations.

Propofol

Because of its short half-life and rapid wake-up time, propofol is the mainstay of sedation in adult intensive care. A propofol bolus given at 1.5–2.5 mg/kg for intubation produces a rapid loss of consciousness. On induction, it can cause respiratory depression and apnoea, and a reduction in systemic blood pressure by reducing systemic vascular resistance.

However, in paediatric intensive care, it has a limited role. There are well-documented reports of serious adverse events and deaths whilst using continuous infusions of propofol in children. Propofol-related infusion syndrome (PRIS) was first reported by Bray [28] and includes hyperkalaemia, metabolic acidosis, hyperlipidaemia, myocardial dysfunction, bradyarrhythmias, rhabdomyolysis and death. Doses of greater than 4 mg/kg/h for more than 48 hours are significant risk factors. Immature hepatic metabolism of the lipid carrier and consequent accumulation and infiltration into the cardiac conduction system are speculated as the cause of the arrhythmias. [29] In 2001 the Committee on Safety of Medicines and the

Medicines Control Agency in the United Kingdom both advised against the use of propofol in children younger than 16 years of age as a continuous infusion on the PICU.

Chloral Hydrate

Chloral hydrate is an orally active agent with sedative–hypnotic properties and is able to produce sedation without significant respiratory depression. It is a prodrug being metabolised to tri-chloroethanol, which is then excreted in the urine. It is a useful enteral agent to supplement IV sedation or it can be effective on its own at 30–50 mg/kg. Its absorption can be variable depending on the activity of the gut. Chloral can be used in neonates but with caution as its metabolites have a longer half-life in this group and it accumulates in renal impairment. It can also cause withdrawal symptoms when used for greater than 7 days if stopped abruptly.

Phenothiazines

Phenothiazines have potent central anticholinergic sedative effects. Antagonism of central acetylcholine synapses and central histamine H_1-receptors may be responsible for their sedative activity. The use of promethazine has declined, whilst alimemazine increases and is usually given orally. Alimemazine is an H_1-histamine antagonist, which is more powerful than promethazine. Given at 1–2 mg/kg it provides good sedation within 30–40 minutes lasting for 4–6 hours. It should be used with caution in neonates, if at all.

Thiopental

Thiopental has a number of uses in the PICU, including the induction of anaesthesia for elective intubation at 2–4 mg/kg, as an infusion (1–5 mg/kg/h) to reduce raised intracranial pressure and in refractory status epilepticus. When used for the latter two conditions, continuous EEG monitoring to ensure burst suppression should accompany it. A retrospective review of eight UK PICUs revealed that thiopentone was the most commonly used anticonvulsant to treat refractory convulsive status epilepticus on admission to the PICU.[30]

Isoflurane

Isoflurane is not a suitable or practical agent to use in the PICU. Occasional case reports continue to surface using tailored devices, such as the Anaesthetic Conserving Device (AnaConDa), a modified heat and moisture exchanger, suggesting it may provide an alternative in difficult cases needing prolonged sedation. [31] However, the use of isoflurane is rare.

Evidence Base for Sedation

Applying the principles of Level of Evidence (Level) and Grade of Recommendation (GRADE) there is very little high-quality evidence to guide the use of sedation in children in the PICU. [32] Reviewing the current literature reveals only two recent systematic reviews [33], [34] that advocate the use of continuous sedation in children (Level 1A, Grade B). As to which sedative agents to use, there have been no validated RCTs to help; only anecdotal evidence is available (Level 5).

There is reasonably good recent evidence (Level 1B, Grade B) supporting the use of clonidine, [35] or dexmedetomidine [36] as continuous IV agents to achieve sedation. The use of dexmedetomidine in neonates has been shown to be safe and effective for up to 24 hours. [24]

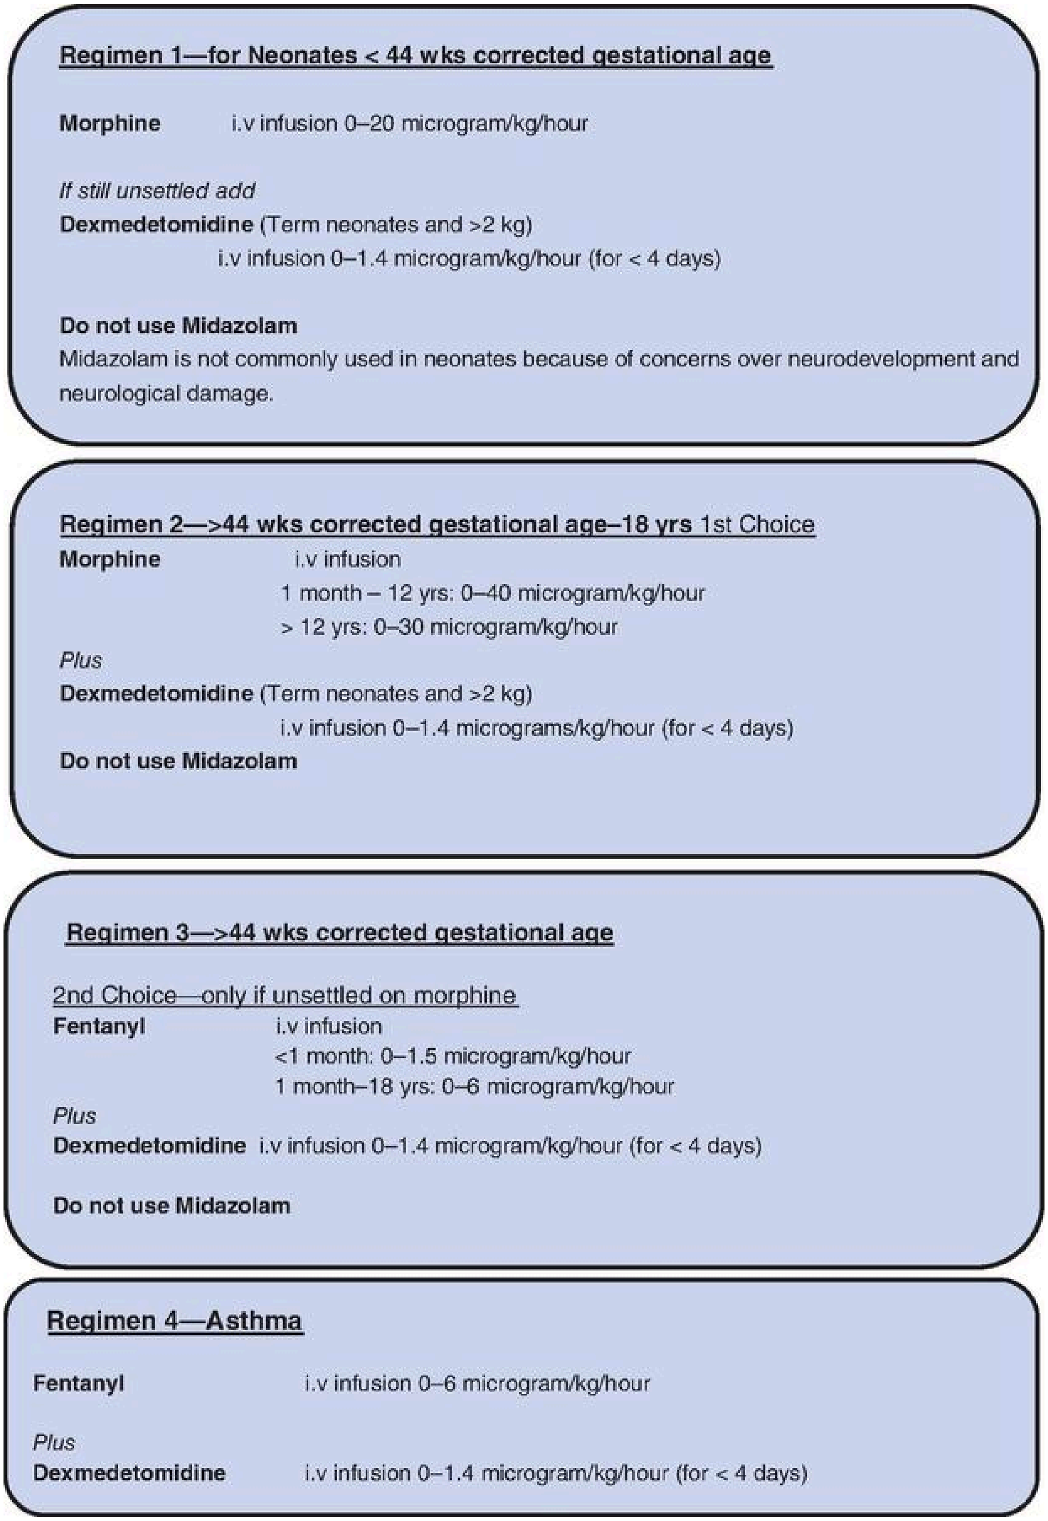
Daily interruption of sedation until the child becomes fully awake [13] or reaches a specific COMFORT score [37] has been shown to significantly reduce the length of mechanical ventilation, the duration of ICU stay and the total dose of midazolam in two recent studies in children (Level 1B Grade B).

Sedation in neonates can be difficult as the developing brain is very vulnerable. A systematic review of the Cochrane database reports that there is insufficient evidence to support the use of midazolam in neonates and that there may be an increased associated risk of adverse neurological effects (Level 1A, Grade A). When IV sedation is needed in neonates, morphine is the single agent of choice and is safer than midazolam (Level 1A, Grade B). [20]

Agents for Analgesia

Morphine

Morphine is the mainstay of analgesia in the PICU and as part of a sedative regimen for children (Fig. 94.1) . Its main action is via μ-receptors in the CNS. In neonates, it is the only agent used and provides sufficient analgesia and sedation. Morphine has several unwanted actions, including respiratory depression even with therapeutic analgesic doses and the release of histamine from mast cells resulting in bronchospasm. The active metabolite, morphine-6-glucuronide further prolongs its activity. The bolus dose is 0.1–0.2 mg/kg and the infusion rate is 10–40 μg/kg/h.



Regimen 1—for Neonates < 44 wks corrected gestational age

Morphine i.v infusion 0–20 microgram/kg/hour

If still unsettled add
Dexmedetomidine (Term neonates and >2 kg)
i.v infusion 0–1.4 microgram/kg/hour (for < 4 days)

Do not use Midazolam
Midazolam is not commonly used in neonates because of concerns over neurodevelopment and neurological damage.

Regimen 2—>44 wks corrected gestational age–18 yrs 1st Choice
Morphine i.v infusion
1 month – 12 yrs: 0–40 microgram/kg/hour
> 12 yrs: 0–30 microgram/kg/hour
Plus
Dexmedetomidine (Term neonates and >2 kg)
i.v infusion 0–1.4 micrograms/kg/hour (for < 4 days)
Do not use Midazolam

Regimen 3—>44 wks corrected gestational age

2nd Choice—only if unsettled on morphine
Fentanyl i.v infusion
<1 month: 0–1.5 microgram/kg/hour
1 month–18 yrs: 0–6 microgram/kg/hour
Plus
Dexmedetomidine i.v infusion 0–1.4 microgram/kg/hour (for < 4 days)

Do not use Midazolam

Regimen 4—Asthma

Fentanyl i.v infusion 0–6 microgram/kg/hour

Plus
Dexmedetomidine i.v infusion 0–1.4 microgram/kg/hour (for < 4 days)

The chart is divided into four outlined rectangular sections labelled Regimen 1, Regimen 2, Regimen 3, and

Regimen 4. Regimen 1 is labelled for neonates less than 44 weeks corrected gestational age and lists morphine as an intravenous infusion with a dose range of 0 to 20 micrograms per kilogram per hour. A note below reads, if still unsettled, add dexmedetomidine for term neonates and those over 2 kilograms with an intravenous infusion range of 0 to 1 micrograms per kilogram per hour for less than 4 days. A warning at the bottom states, Do not use Midazolam and explains that Midazolam is not commonly used in neonates because of concerns over neurodevelopment and neurological damage. Regimen 2 is labelled for more than 44 weeks corrected gestational age to 18 years as the first choice and lists morphine with intravenous infusion. For ages 1 month to 12 years, the dose is 0 to 40 micrograms per kilogram per hour, and for over 12 years it is 0 to 30 micrograms per kilogram per hour. Dexmedetomidine for term neonates over 2 kilograms is added with a dose of 0 to 1 point 4 micrograms per kilogram per hour for less than 4 days. A note below states Do not use Midazolam. Regimen 3 is also for more than 44 weeks corrected gestational age and is labelled second choice only if unsettled on morphine. Fentanyl is listed for intravenous infusion. For under 1 month, the dose is 0 to 1 point 5 micrograms per kilogram per hour, and for 1 month to 18 years, the dose is 0 to 6 micrograms per kilogram per hour. Dexmedetomidine is added with an intravenous infusion of 0 to 1 point 4 micrograms per kilogram per hour for less than 4 days. A note again states, do not use Midazolam. Regimen 4 is labelled Asthma and lists fentanyl with intravenous infusion at a dose of 0 to 6 micrograms per kilogram per hour and dexmedetomidine with the same intravenous infusion dose of 0 to 1 point 4 micrograms per kilogram per hour for less than 4 days.

Regimen 5 – Neuroprotection

1st choice **Remifentanil**
i.v. infusion 1 month–12 yrs: 3–80 microgram/kg/hour
>12 yrs: 3–45 microgram/kg/hour*
*(max. 120 micrograms/kg/hr)

2nd choice **Morphine** (if >3 days)
i.v infusion <12 yrs: 0–40 microgram/kg/hour
>12 yrs: 0–30 microgram/kg/hour

Or if unsettled (<18 yrs)
3rd Choice **Fentanyl** i.v. infusion 0–6 microgram/kg/hour
Plus
Dexmedetomidine i.v. infusion 0–1.4 microgram/kg/hour (for < 4 days)

Paralysis is not always needed if patient adequately sedated and ICP stable.
Vecuronium
i.v. infusion <17 yrs: Initially: 0–2 microgram/kg/min
(max 3.3 microgram/kg/min)
Adult usual max: 1.4 microgram/kg/min

Alternative Agents

Propofol – consider before use.
i.v. infusion >16 yrs: 0.3–4 milligrams/kg/hr
(>4 milligrams/kg/hr and >48 hrs = significant risk of propofol infusion syndrome)

Midazolam – avoid use as an infusion - except for seizure control.
i.v. sedative bolus dose is 50–100 micrograms/kg
Enteral dose 500 micrograms/kg (max 20 milligrams if >40kg)

i.v. infusion:
1 month–12 yrs: 0–4 microgram/kg/minute
(Start at 0–2 microgram/kg/min and titrate according to response)
12–17 yrs: 0–3.3 micrograms/kg/minute
(Higherdoses may be used in status epilepticus)

Clonidine
i.v.infusion 0–2 micrograms/kg/hour (max. 100 microgram/hour)
Weaning: Stop if used <2 weeks. If >2 weeks reduce over 5 days.

Chloral Hydrate
Enteral/PR dose 15–50 milligrams/kg 6 hourly (max. 1 g per dose)
(max. 15 milligrams/kg/dose in self ventilating children)

Thiopental Sodium - discuss with consultant before use
i.v. infusion 1–8 milligrams/kg/hour

Rocuronium
>1 month–17 yrs: 300–600 microgram/kg/hour

The chart titled Regimen 5 Neuroprotection is divided into two sections. The first section lists sedative medication regimens in order of preference, beginning with the first choice of remifentanil, administered via intravenous infusion. For patients aged one month to twelve years, the dosage is three to eighty micrograms per kilogram per hour. For patients older than twelve years, the dosage is three to forty five micrograms per kilogram per hour, with a maximum of one hundred twenty micrograms per kilogram per hour. The second choice is morphine, recommended if the patient is less than three days old, administered via intravenous infusion. For patients under twelve years, the dose is zero to forty micrograms per kilogram per hour, and for those over twelve years, it is zero to thirty micrograms per kilogram per hour. If the patient is unsettled and under eighteen years of age, the third choice is fentanyl at a dose of zero to six micrograms per kilogram per hour via intravenous infusion, plus dexmedetomidine administered at zero to one point four micrograms per kilogram per hour intravenously for less than four days. A note below this states that paralysis is not always needed if the patient is adequately sedated and intracranial pressure is stable. Under this, the muscle relaxant Vecuronium is listed for patients under seventeen years, with an initial dose of zero to two micrograms per kilogram per minute via intravenous infusion, with a maximum of three point three micrograms per kilogram per minute. The adult usual dose is one microgram per kilogram per minute. The second section is titled Alternative Agents. It lists various sedatives and anaesthetics with their recommended dosages. The first is propofol, to be considered before use for patients older than sixteen years, at a dose of zero point three to four milligrams per kilogram per hour. A note indicates that doses greater than four milligrams per kilogram per hour and durations longer than forty-eight hours carry a significant risk of propofol infusion syndrome. The next is midazolam, which should be avoided as an infusion except for seizure control. The intravenous sedative bolus dose is fifty to one hundred micrograms per kilogram. The enteral dose is five hundred micrograms per kilogram with a maximum of twenty milligrams for patients over forty kilograms. Intravenous infusion dosages are specified for different age groups. For one month to twelve years, the dose is zero to zero point four micrograms per kilogram per minute, starting at zero point two micrograms per kilogram per minute and titrated according to response. For ages twelve to seventeen years, the dose is zero to three point three micrograms per kilogram per minute. A note mentions that higher doses may be used in status epilepticus. Clonidine is next, administered via intravenous infusion at zero to two micrograms per kilogram per hour, with a maximum of one hundred micrograms per hour. A note on weaning states to stop it if used for less than two weeks, and if used for more than two weeks, reduce over five days. Chloral hydrate is administered enterally or rectally at doses of fifteen to fifty milligrams per kilogram every six hours, with a maximum of one gram per dose and a maximum of fifteen milligrams per kilogram per dose in self-ventilating children. Thiopental Sodium is to be discussed with a consultant before use and is administered via intravenous infusion at one point eight to eight milligrams per kilogram per hour. Rocuronium is listed at the bottom for patients over one month to seventeen years, with a dose of three hundred to six hundred micrograms per kilogram per hour.

FIG. 94.1 Suggested analgosedation regimens for children in intensive care.

Nurse or patient-controlled analgesia devices are very useful following surgery. They can deliver a continuous background infusion of a fixed dose of opioid and allow the patient or nurse to administer an extra dose at fixed time intervals if more analgesia is required.

Fentanyl

Fentanyl is 100 times more potent than morphine; it is cardiovascularly stable over a wide range of doses and is a frequent substitute for morphine. An induction dose of 1–2 µg/kg IV is sufficient for intubation, and infusions of 1–6 µg/kg/h produce effective analgesia in children and neonates on mechanical ventilation. Fentanyl causes dose-dependent respiratory depression and at very high doses it can produce chest wall rigidity. A bolus is often helpful prior to painful procedures in neonates with pulmonary hypertension.

Differences in responses to opioids and opioid requirements have been attributed to the ABCB1 genotype.[38] Fentanyl effectiveness and metabolism may be influenced by genetic polymorphisms. The gene ABCB1 encodes p-glycoprotein, an efflux pump capable of transporting certain opioids, including fentanyl. Less fentanyl was needed in children with the AA allele at ABCB1 locus rs1045642 compared with patients with the AG or GG allele. ABCB1 single nucleotide polymorphism, rs1045642 genotype AA, was associated with reduced fentanyl requirements in a diagnostically diverse sample of PICU patients, possibly because of decreased expression and activity of p-glycoprotein.[39]

Remifentanil

Remifentanil is an ultrashort-acting potent synthetic opioid 10 times more potent than fentanyl and 1000 times more potent than morphine. It is ideal for stimulating procedures such as physiotherapy or chest drain removal. It is also ideal for neuro-sedation because of its short half-life. It can be stopped briefly to produce a window of consciousness allowing neurological assessment.

Following initial redistribution, remifentanil is metabolised rapidly via non-specific esterases. Having a context-sensitive half-time of 3–5 minutes, its duration of action is not influenced by the total time of infusion. Rates of infusion of 3–80 µg/kg/h produce satisfactory analgesia and sedation in ventilated children aged 1 month to 12 years and for those over 12 years of age 3–120 µg/kg/h.

The use of remifentanil in children and neonates in intensive care is increasing.[40] In an RCT of neonates and infants, the authors concluded that remifentanil could be the ideal opioid for analgesia and sedation for mechanically ventilated neonates and infants.[41]

Here too, gene polymorphisms of the serotonin transporter gene (a functional 43 bp insertion/deletion polymorphism of serotonin transporter gene (5-HTTLPR), rs25531) may contribute to the variation of analgesic response to remifentanil. Individuals with 5-HTTLPR low expression genotype gain more pain relief from remifentanil than individuals with 5-HTTLPR high expression genotype.[38]

Methadone

Methadone is a long-acting synthetic opioid agonist used predominantly in adults to treat addiction to other opioids. It is also used in the adult intensive care environment to prevent or minimise withdrawal symptoms from morphine and fentanyl. It is a mu-receptor agonist with high enteral bioavailability and long duration of action. A review of the efficacy and safety of methadone in adult and paediatric ICU supported its use in weaning opiates but recognised there was limited evidence of this assertion.

[42] However, a systematic review of 12 studies involving 459 paediatric patients with varying tapering times from 4 to 26 days could not find sufficient evidence to recommend the use of methadone above any other weaning technique. [43] Side effects include prolongation of corrected QT interval and serotonin syndrome.

Paracetamol and Non-Steroidal Anti-Inflammatory Drugs

The mechanism of action of paracetamol in providing analgesia is still not fully elucidated. The primary site may be inhibition of prostaglandin synthesis by inhibiting cyclooxygenases (COX). However, other mechanisms independent of the COX enzyme are now becoming apparent including activation of descending serotonergic pathways and central actions mediated by the formation of the bioactive AM404 metabolite. [44] The intravenous dose for paracetamol in infants weighing less than 10 kg is 7.5 mg/kg every 6 hours; in children, it is 15 mg/kg and the total daily IV dose should be limited to 60 mg/kg. The oral dose is 20–30 mg/kg for one dose, then 15–20 mg/kg/day up to 60 mg/kg/day. Higher doses are required when used rectally, 30–40 mg/kg initially then 15–20 mg/kg 6 hourly to a maximum of 60 mg/kg/day. Paracetamol is metabolised in the liver and renally excreted.

Non-steroidal anti-inflammatory drugs (NSAIDs) are less commonly used in the PICU. The cyclo-oxygenase (COX) enzymes sensitise peripheral nerve endings to agents such as histamine and bradykinins by increasing prostaglandin levels. NSAIDs work by inhibiting COXs and thus blocking the production of prostaglandin. There are two types of NSAIDs, non-selective NSAIDs that block cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2), an example being ibuprofen and selective NSAIDs blocking just COX-2, such as celecoxib. Generally, only the non-selective NSAIDs are used in the PICU but celecoxib is emerging as a useful option. Careful patient selection is needed because of concerns over compromising renal function, increasing bleeding tendency and gastrointestinal problems. The advantages of NSAIDs include avoiding the unwanted symptoms of opioids such as nausea, vomiting, pruritus, respiratory depression, tolerance, withdrawal, sedation and urinary retention. [45]

Evidence Base for Analgesia

There is evidence for using continuous IV opioid infusions (Level 2B, Grade B). Continuous morphine therapy appeared to be effective in controlling neonatal postoperative pain, as judged by nursing observations. [46]

The combination of opioid and non-opioid analgesia is supported by work from Wong [47] who undertook a systematic review of 31 RCTs and concluded that multiple doses of NSAIDs on a background of continuous opioid infusion gave significant benefit (Level 2B, Grade A).

Patient-controlled analgesia (PCA) has not been rigorously evaluated in terms of advantage over any other form of intermittent analgesia. However, a meta-analysis of 49 studies revealed children using PCA had lower visual analogue scale pain intensity scores than children who did not receive PCA (Level 1B, Grade B). [48]

A recent Cochrane review of eight trials and 614 infants concluded that paracetamol may reduce the total need for morphine following major surgery and when combined with morphine it is useful in severe pain. [49]

Sucrose in Neonates

There is good evidence for the beneficial effect of 0.5 mL sucrose (24%) in reducing heel-prick pain and 2 mL is useful in reducing venipuncture and intramuscular injections. However, the effectiveness of sucrose for reducing pain/stress from other interventions, such as arterial puncture, subcutaneous injection, insertion of nasogastric or orogastric tubes, bladder catheterisation, eye examinations and echocardiography examinations, was inconclusive. [50]

Withdrawal Syndromes

Apart from the morbidity from the reason for admission to PICU, significant morbidity also can result from the treatments administered whilst in PICU. Iatrogenic withdrawal symptoms and delirium are now the main causes of morbidity during weaning and after leaving PICU. [51]

IWS is a well-recognised problem in children receiving benzodiazepines and opioids for periods greater than 5 days. Recent work suggests that monitoring for withdrawal should start as early as 3 days and that rates of infusion of midazolam greater than 0.35 mg/kg/h or 6 µg/kg/min will put children at high risk of withdrawal. [52] Infusion of fentanyl for greater than 5 days or a total dose greater than 1.5 mg/kg is associated with greater than 50% incidence of withdrawal. [53] The Sophia observation withdrawal symptoms scale is a useful tool when weaning from sedation/analgesia, [54] as is the withdrawal assessment tool-1 (WAT-1). [55], [56]

Iatrogenic withdrawal symptoms from opioids and benzodiazepines in neonates and children can develop after as short a period as 72 hours of administration. [57] However, the assessment and treatment of IWS varied widely across Europe when surveyed. [58] Across 27 European countries, only 215 (60%) of PICUs reported monitoring for IWS mostly using the WAT-1 (53%).

Management of Delirium

Delirium has a multifactorial pathophysiology but a significant component of this is iatrogenic, namely the intensive care environment where critically ill children are treated. Cognitive, physical and mental health difficulties in children after leaving intensive care were described as post intensive care syndrome (PICS-p). [59] In the paediatric setting a systematic review of 19 studies following up children after hospital discharge revealed a significant minority (30%) who developed neurocognitive and psychological morbidity, including post-traumatic stress disorders (PTSD). [60] Delirium, lack of mobility and heavy sedation are important contributors to the child developing PICS-p. Liberation bundles including delirium screening, limited use of benzodiazepine and early mobilisation are now being proposed. [61]

Delirium is a problem following PICU admission resulting in significant cognitive impairment on leaving intensive care. Delusional memories were reported in almost one-third of children following their PICU admission and were associated both with the duration of opiates/benzodiazepines and an increased risk of developing post-traumatic stress. [62] A significant minority of school-aged children admitted to the PICU are at risk of reduced mental and physical well-being in the short term. [63]

Two validated bedside tools help to incorporate delirium monitoring into the critical care setting. The preschool confusion assessment method for the ICU (psCAM-ICU) identifies delirium in critically ill infants and children less than 5 years of age. The paediatric confusion assessment method for the intensive care unit (pCAM-ICU) assesses delirium in children 5 years of age and older. [64] The ps/pCAM-ICU was adapted from the adult confusion assessment method for the ICU (CAM-ICU). [65] In practice the RASS is used to measure the sedation level prior to using other tools such as the Cornell assessment of paediatric delirium (CAP-D) or pCAM-ICU to assess delirium. [66]

Antipsychotic agents may have a limited role in improving the symptoms of delirium in ICU. A review of 13 reports of the use or antipsychotic agents in 370 children concluded there was some improvement in delirium symptoms. However, these reports each contained only small numbers of patients and only 5 assessed delirium with a validated tool. Agents used include haloperidol (n =131), olanzapine (n =125), quetiapine and risperidone, with significant variation in doses administered. [67] Risperidone has been used on children as young as 2 years of age to manage delirium and was found to be safe and well tolerated at daily doses of 0.1–0.25 mg in 1 or 2 doses per day. [68]

Melatonin has been used to alleviate symptoms of delirium. The value of using melatonin to reduce the incidence and duration of delirium is unclear. A meta-analysis encompassing 14 studies in 1712 adults concluded that melatonin significantly reduced the incidence of delirium by 34% in ICU patients, though it did not reduce the duration of delirium when it occurred, nor the length of ICU or hospital stay. There was an improvement in sleep quality, better sedation scores and a lower requirement for sedation. [69] However, in a prospective RCT of 847 adults the prophylactic use of melatonin for delirium in adult intensive care could not demonstrate any significant difference in the average proportion of delirium-free periods or quantity and quality of sleep between those who received melatonin and a placebo group. Nor was there any difference in mortality or length of ICU or hospital stay. The authors concluded that enteral melatonin started 48 hours into an ICU admission did not reduce the incidence of delirium. [70] In a small retrospective study, 63 paediatric patients received melatonin to reduce delirium, 39 later required additional antipsychotics with risperidone being the most frequently used agent. Melatonin did not appear to decrease the use of antipsychotic agents questioning its value in delirium in children. [71]

Improving Quality of Care

The avoidance of the inertia of sedation infusions leading to oversedation, delirium and immobility leading to functional impairment and PICU-acquired complications should be considered as new markers of the quality of care provided. [72] The ICU Liberation Collaborative is a quality improvement package designed to liberate patients from iatrogenic aspects of ICU care. [51] The collaborative produced a bundle of strategies with the acronym ABCDEF to improve the outcome of many variables in the patient’s ICU journey. The ABCDEF bundle was implemented in 76 adult ICUs and assessed in 15,000 adults. The bundle consists of **A** ssess, prevent and manage pain; **B** oth spontaneous awakening and breathing trials: **C** hoice of Analgesia and Sedation; **D** elirium assess, prevent and manage; **E** arly Mobility and Exercise; **F** amily engagement/empowerment. Use of the ABCDEF bundle resulted in significant improvements in survival, ventilation usage, delirium and PICS. [73] Implementation of a liberation bundle in PICU is also possible, prioritising delirium screening and treatment, benzodiazepine-limited sedation and early mobilisation. [61]

Regional Techniques

Although a number of regional blocks are described, the most commonly encountered regional block used for postoperative pain is the lumbar epidural. The procedure is usually performed in the operating theatre and is not commonly instituted in the PICU.

Holistic Approach

Non-pharmacological strategies to promote a normal day-night, sleep–wake cycle include maintaining a quiet environment and natural light during the day and no artificial light during the night. Measures such as eye masks, earplugs and other noise reduction strategies can potentially decrease the need for chemical and physical restraints [74] and single rooms improve the quality of sleep and reduce the prevalence of delirium in the adult ICU setting. [75]

Developments in the adult ICU world often lead the way and guide us to attempt to make the child's stay in the PICU as normal as possible. A comparison of no sedation agents with light sedation with daily interruptions of sedation aiming for an RASS score of -2 to -3 could find no significant difference between the two groups. The non-sedation group had one more day free from delirium with the primary outcome of mortality at 90 days and secondary outcomes of number of days free from delirium. [76] In PICU the use of physical restraints with elbow splints and mittens to prevent self-extubation has superseded chemical restraints. The practice of light sedation will be more challenging in the paediatric population but awareness of techniques to provide light sedation and its significant advantages should make it the goal of the PICU.

Neuromuscular Blocking Agents

The responses to neuromuscular blocking agents and the physiology that underlie them differ between adults and children and even across the age range of the paediatric population from neonates and infants to children. Development of innervation of skeletal muscle and acetylcholine (ACh) receptor starts very early in gestation. It is only at 24–31 weeks do neuromuscular (NM) junctions begin to resemble a mature structure which continues to develop until one year of life. [77]

Fetal nicotinic receptors are more sensitive to and stay open longer when stimulated by ACh. This is a useful feature as there are reduced stores of the transmitter in the fetal period. At birth, there is only about a third of the amount of ACh present making NM transmission less effective [78] resulting in an increased sensitivity to non-depolarising NM blockers yet with a relatively normal response to succinylcholine.

Depolarising Agents

Succinylcholine

There is an increased dose requirement for succinylcholine in younger children due to immature NM junctions and an increased volume of distribution seen in this age group. Dose-response curves indicate infants may require up to 3 mg kg^{-1} and children 2 mg kg^{-1}.[79] Neonates and infants up to 6 months of age have only about 50% the concentration of butyrylcholinesterase but this does not cause a prolongation in the effects of succinylcholine. The side effects are similar to adults including hyperkalaemia and malignant hyperthermia. This led in 1994 to the US Food and Drug Administration (FDA) recommending that succinylcholine in children should be reserved for emergency intubation and cases when immediate securing of the airway is necessary.

Non-depolarising Relaxants

Neonates and infants have increased sensitivity at the neuromuscular junction as the result of a reduction in ACh release from immature motor nerves, resulting in less blocking agent needed to produce a 50% depression of electromyography (EMG) twitch (D_{50}) giving the impression that neonates and children were more sensitive to NM blockers. However, when the increased volume of distribution for the relevant paediatric age groups was compensated for it became clear that D_{50} is the same for children and adults.

Benzylquinoliniums

Atracurium

Atracurium has a lower effective dose (ED_{95}) in neonates and infants than in children with a more rapid onset following a 0.5 mg kg^{-1} dose. Neonates have a more rapid recovery than infants and children.[80] It has similar adverse effects profile as in adults, mainly histamine release.

Cisatracurium

An isomer of atracurium, it has similar properties and also undergoes spontaneous Hoffman elimination. A dose of 0.1 mg kg $^{-1}$ in the blockade is faster in infants than children (2.0 vs. 3.0 min), whereas recovery is longer (36 vs. 43 min). [81] Infants were found to have a longer recovery time by up to 5–10 minutes after the same dose. Onset and recovery are shorter in all groups compared to adults. Cisatracurium is the agent of choice for many paediatric anaesthetists.

Mivacurium

With a similar structure to atracurium, it has a shorter duration of action being metabolised by butyrylcholinesterases. There is a faster recovery time in infants and children than in adults because of faster plasma clearance in the young. A dose of 0.2 mg kg $^{-1}$ produces good intubation conditions in about 90 seconds. In 562 paediatric patients, aged 2 months to 14 years, onset time of a dose of 0.2 mg kg $^{-1}$ was faster in neonates and infants compared to children aged 13 months to 14 years. [82]

Aminosteroids

Pancuronium

Infrequently used in general paediatrics, though it used to be a favourite in cardiac anaesthesia in this group who are at risk of bradycardia and hypotension on induction. It produces a 30%–40% increase in heart rate due to its vagolytic effects and a 10%–15% increase in rate-dependant systolic pressure. A dose of 0.2 mg kg $^{-1}$ produces relaxation in about 2 minutes.

Vecuronium

The ED $_{95}$ for vecuronium is lower in neonates and infants than children and has a longer duration of action, almost double for a 0.1 mg kg $^{-1}$ dose, lasting 60 minutes versus 18 minutes. [83] Care should be taken as it is longer acting in neonates and infants.

Rocuronium

Favoured for its rapid onset, a dose of 0.6 mg kg $^{-1}$ lasts longer in neonates and infants than in children. Intubating conditions are satisfactory in 60 seconds in children. This is now the agent of choice by most paediatric anaesthetists.

Summary

The purpose of sedation and analgesia in children whilst in the PICU is to reduce pain, anxiety and distress. We are moving away from an era where chemical restraint is the standard of care. We need to adapt to novel measures that allow children to be comfortable and pain free yet interactive whilst being ventilated. Almost as important they should not suffer from iatrogenic complications caused during and following their stay in the PICU. Symptoms of withdrawal and delirium are our major challenges following discharge. The child's need for the PICU should not be further complicated by problems caused by the sedation and analgesia we administer.

Shock and cardiac disease in children

Charles Larson

Shock

Shock is the clinical state resulting from insufficient oxygen delivery to meet oxygen demand, and is described in detail in Chapter 23 . Shock in children is most commonly due to hypovolaemia or sepsis and remains an important cause of infant and child mortality globally. The cellular effects of tissue hypoxia in shock are the same in children and adults, but there are important developmental changes in anatomy, physiology and immunity during childhood, which influence the incidence, presentation and natural history of shock.

Developmental Differences

Body Fluid Compartments

Although the extracellular fluid volume in children is greater than in adults when indexed to body weight, the small absolute volumes involved are critical when blood or fluid loss causes shock; 100 mL blood loss is inconsequential for an adult, but represents one-third of the blood volume for a neonate.[1]

Cardiac

There are many differences between the newborn and the mature heart that have important effects on function, particularly under stress. The newborn heart has a relatively small left ventricular muscle mass that must cope with the newly imposed demands of systemic circulation. In response to increased afterload, the neonatal myocardium increases in mass by both hypertrophy and hyperplasia, with the capacity for the latter of these mechanisms being lost after the first 6 months of life. Neonatal cardiac myocytes appear small and blunted with a higher proportion of non-contractile elements than mature myocytes. The fewer myofibrils are poorly aligned and there are sparser, disorganised-looking mitochondria. Less efficient handling of calcium by the myocyte membrane and sarcoplasmic reticulum makes the neonatal myocyte more dependent on extracellular fluid calcium concentration, which may contribute to limited cardiac reserve. [2]

The physiological consequence is a stiffer, less compliant ventricle that is less able to generate contractile force. Physiological changes at birth (see later) increase both volume and pressure load to the left ventricle. The ability of the ventricle to increase output in response to further volume or pressure loading is limited. [3] The neonatal heart functions at a high state of beta-adrenergic stimulation and therefore has a restricted capacity to increase contractility and rate. Following birth, there is a steady increase in stroke volume index and cardiac index over the first 3 years of life.

Vascular

Antenatal pulmonary blood flow is low (<10% of combined ventricular output) through a relatively muscularised high-resistance circulation. Blood ejected by the right ventricle is mostly diverted through the ductus arteriosus to the systemic circulation. Pulmonary vascular resistance (PVR) falls abruptly at birth with a concomitant increase in pulmonary blood flow. The PVR then falls more slowly, nearing adult levels over the next 6 weeks as a result of pulmonary vascular remodelling. [4] The increase in pulmonary blood flow immediately following birth results in increased preload to the left ventricle. With the clamping of the umbilical cord, the low-resistance placental circulation is removed and the systemic vascular resistance rises acutely, causing an increase in systemic arterial pressure. Following the transition from foetal to neonatal circulation, the systemic vascular resistance index remains relatively constant throughout early childhood. [5]

Microcirculation

There are animal and human data to support the notion of maturation of microcirculation. [6, 7] The infant and young child's microcirculation is leakier at baseline and functions at a higher turnover of fluid and protein than the adult. This state of higher turnover may predispose the child to greater capillary leak in response to inflammatory and traumatic stimuli, resulting in hypovolaemic shock.

Immunity and the Inflammatory Response

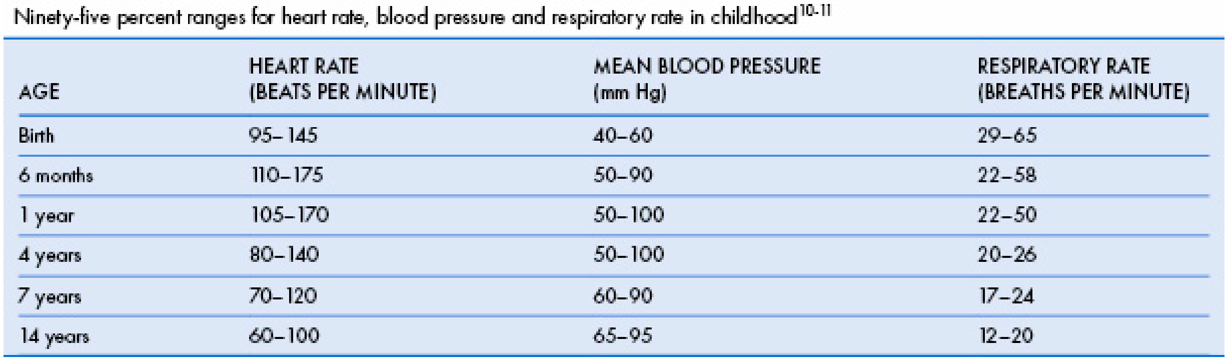
The newborn has had little prior exposure to pathogens and has limited capacity to respond to infection, so is at increased risk of invasive infection. This risk persists beyond the newborn period as the immune system remains immature through infancy and early childhood, with deficits in both innate and adaptive immunity. In addition to immature barriers to infection, infants have lower levels of circulating complement components and defective natural killer cell function. A mature pattern of cytokine and chemokine production is not attained until later in childhood. B cells are geared towards producing immunoglobulin (Ig)M rather than IgG or IgA, and there are multiple distinct deficiencies in T-cell function. [8] The inflammatory response to sepsis also appears to undergo complex developmental changes, the implications of which are hard to define. [9] Aspects of the pro- and anti-inflammatory response are qualitatively and quantitatively different in children compared to adults, including a relative exaggeration of the anti-inflammatory response.

Like adults, children are placed at risk of infection by therapeutic immunosuppression, but there are also a large number of congenital diseases that are characterised by generalised or specific defects in immune function.

Recognition of Shock

Recognition of early shock is very important as children compensate well initially, but their capacity to do so is rapidly exhausted and decompensation can then be sudden; during the early stages of compensated shock in infants, signs may be limited to tachycardia and tachypnoea (Table 95.1). Hypotension is a late finding and demands urgent attention. [10], [11]

Table 95.1



Ninety-five percent ranges for heart rate, blood pressure and respiratory rate in childhood[10-11]

AGE	HEART RATE (BEATS PER MINUTE)	MEAN BLOOD PRESSURE (mm Hg)	RESPIRATORY RATE (BREATHS PER MINUTE)
Birth	95–145	40–60	29–65
6 months	110–175	50–90	22–58
1 year	105–170	50–100	22–50
4 years	80–140	50–100	20–26
7 years	70–120	60–90	17–24
14 years	60–100	65–95	12–20

Initial Assessment and Investigation

History

- Fever, feeding, urine output, diarrhoea, vomiting
- Rapid breathing, sweating, tiring whilst feeding
- Irritability, lethargy
- Trauma, including the potential for non-accidental injury
- Potential for ingestion
- Vaccination history.

Examination

- Temperature

- Conscious level
- Peripheral perfusion, capillary refill
- Rash
- Skin turgor
- Mucous membranes
- Pulses
- Heart rate, rhythm
- Blood pressure
- Respiratory rate.

Initial Investigations

- Chest X-ray
- Arterial blood gas with blood lactate
- Full blood count and film examination
- Blood glucose
- Plasma electrolytes, urea, creatinine, liver function tests.
- Inflammatory markers such as procalcitonin or C-reactive protein

If there is evidence of sepsis or if there is no obvious cause for shock, take cultures and start antibiotic therapy.

- Blood cultures – peripheral blood and from any lines already in place
- Urine cultures (in–out urinary catheter or suprapubic aspirate in young infants)
- Throat swab
- Nasopharyngeal aspirate, stool and blood for virology
- Do not do a lumbar puncture in a shocked child. Commence antibiotics following other cultures. Cerebrospinal fluid for bacterial and viral culture and polymerase chain reaction can be obtained later.

Types of Shock

The traditional classification of shock (Chapter 23) is valid in children, but a combination of these is likely to be present in any given clinical situation. In particular, it is best to think of septic shock as a clinical entity that incorporates features of several shock types.

Hypovolaemic Shock

This is a common presentation in childhood, which is frequently secondary to water and electrolyte losses with diarrhoea and vomiting.

The initial compensatory response to hypovolaemia is an increase in catecholamine secretion, leading to reduced peripheral perfusion, tachycardia and normal blood pressure with diminished pulse pressure. Lethargy and tachypnoea secondary to increasing metabolic acidosis are variably present. Up to 15%–20% of the circulating blood volume may be lost before hypotension occurs. With further volume loss, end-organ perfusion and oxygen delivery are compromised leading to worsening acidosis, altered consciousness, oligo/anuria and ultimately myocardial dysfunction.

The cause of hypovolaemia is usually evident from the history and examination, but hidden blood loss must be considered, particularly in infants where unreported head or abdominal trauma may have occurred with few external signs.

Treatment

Ensure adequate airway protection and breathing and administer oxygen. After the establishment of intravenous (or intraosseous) access, early and aggressive intravenous fluid resuscitation is vital to restore the circulating blood volume. Give fluid (10–20 mL/kg of a balanced crystalloid solution per bolus) rapidly with frequent clinical reassessment to verify signs of reversal of shock.[12, 13] Give blood if the shock is due to ongoing blood loss.

Cardiogenic Shock

Cardiogenic shock can be difficult to distinguish from septic shock. Causes of cardiogenic shock are listed in Box 95.1 . Children tend to present with tachycardia, low pulse volume and poor peripheral perfusion as vasoconstriction maintains blood pressure in the initial stages. Tachypnoea, obtundation and decreased urine output are present early. Examination may reveal a gallop rhythm, hepatomegaly, sweating and peripheral oedema. The presence or absence of a cardiac murmur is unlikely to be helpful in acute diagnosis. Ongoing shock leads to progressive hypoperfusion of end organs.

Box 95.1

Causes of cardiogenic shock

- Primary cardiac disease
    - Congenital heart disease
    - Post cardiac surgery
    - Cardiac trauma
    - Myocarditis
    - Cardiomyopathy
    - Arrhythmias and conduction defects
    - Endocarditis
- Local disease with cardiac effects
    - Constrictive pericarditis
    - Pericardial tamponade
    - Compression of heart by tumour, tension pneumothorax
- Systemic disease with cardiac effects
    - Sepsis
    - Hypoxic-ischaemic injury
    - Autoimmune disease
    - Kawasaki disease
    - Drug ingestion

Investigation

Initial investigations include chest X-ray, electrocardiogram (ECG) and echocardiogram, with further tests prompted by individual findings. Take blood cultures and start antibiotics if there is no known cause for cardiogenic shock.

Treatment

Treatment is aimed at medically and surgically addressing reversible causes of myocardial dysfunction and supporting cardiac output with inotropes, afterload reduction and judicious use of intravenous fluids. Consider ECMO early if the patient is deteriorating and unresponsive to therapy.

Distributive Shock

Causes

These include anaphylaxis, spinal cord injury or administration of vasodilators. Septic shock in children may have a distributive component, but this is not as common a finding as in adults (see in the following sections).

Presentation

In distributive shock, tissue perfusion is inadequate despite an initially normal circulating blood volume and normal (or high) cardiac output. Abnormal vasomotor tone with profound vasodilatation leads to a reflex tachycardia; in spinal cord injury absence of sympathetic activity may result in bradycardia. Examination reveals warm peripheries, tachycardia and hypotension with a wide pulse pressure. The cause of distributive shock is likely to be clear from clinical examination.

Treatment

Attend to airway and breathing, obtain intravenous access and give rapid fluid boluses (10–20 mL/kg). If there is inadequate reversal of shock then vasopressors may be necessary to restore blood pressure (or counteract the effects of vasodilator drugs). Anaphylaxis must be treated specifically and urgently.

Obstructive Shock

Causes

These include pericardial tamponade, tension pneumothorax, pulmonary embolus and mediastinal mass.

Presentation

In obstructive shock, extracardiac restriction of cardiac output prevents adequate oxygen delivery. There may be obstruction to the pulmonary or systemic outflow tract or circulation or compression by pericardial tamponade or tension pneumothorax.

Treatment

Treatment is aimed at ensuring adequate circulating volume and identifying and remedying the cause of the obstruction. Tamponade and tension pneumothorax require urgent drainage.

Septic Shock

The International Consensus Criteria for Pediatric Sepsis and Septic Shock define paediatric sepsis as organ dysfunction in children with suspected or confirmed infection. Septic shock exists in children with sepsis and cardiovascular dysfunction. [15] Hospital mortality from paediatric septic shock is 11%–33%, with higher mortality rates reported in lower-resource settings. [15] A significant proportion of sepsis survivors exhibit a new functional disability. [16-17] The clinical presentation of septic shock in young children is different in adults, who reliably present with peripheral vasodilation, hypotension and a relatively high cardiac output. The picture in children is more commonly dominated by myocardial depression and peripheral vasoconstriction. [18] Hypovolaemia occurs rapidly due to a capillary leak secondary to the sepsis-induced inflammatory response.

Following the COVID-19 pandemic, the epidemiology of septic shock has shifted. A multiple-fold increase in children with severe septic shock due to invasive group A Streptococcus has been seen globally, including presentations of toxic shock, empyema and necrotising fasciitis. [19] They commonly have viral co-infections, which have seen an equal resurgence. It is unclear how such trends will evolve in the coming years.

Treatment

Despite the concerns raised by the findings of the mortality after fluid bolus in African children with severe infection (FEAST) trial,[20] current guidelines for the treatment of septic shock in regions with access to PICU-level care continue to emphasise the importance of prompt and aggressive fluid resuscitation, along with the early institution of vasoactive therapy.[21],[22]

Airway

Administer supplemental oxygen to all children with shock and intubate those unable to protect their airway or who have impending respiratory failure.

Circulation and Access

If peripheral access is difficult and the child is obtunded or severely shocked, consider intraosseous access early. Give fluid boluses of 10 mL/kg to restore circulating blood volume. Patients who do not have a reversal of signs following 40–60 mL/kg of fluid, gain central venous access. This allows the administration of inotropes or vasoconstrictors, measurement of central venous pressure and measurement of central venous saturation (see below). Insert an arterial line for frequent sampling and invasive monitoring of blood pressure.

Previous guidelines distinguished between ‘cold’ and ‘warm’ shock on physical examination, favouring inotropes for ‘cold’ shock and vasopressors for ‘warm’ shock. However, these classifications correlate poorly with measures of cardiac index and systemic vascular resistance. A low central venous saturation can reliably indicate inadequate oxygen delivery, whereas a normal central venous saturation >70% either suggests adequate tissue oxygen delivery or cellular dysoxia. Echocardiography can also inform fluid, inotrope and vasopressor management by allowing assessment of cardiac filling, contractility and PVR. Invasive measurement of cardiac output is rarely performed in children; pulmonary artery catheter insertion is technically difficult and although several non-invasive methods are available to estimate cardiac output in children, none is widely used.

Inotrope/Vasodilator/Vasoconstrictor Therapy

Do not delay starting vasoactive drugs if there is difficulty gaining central venous access. Dilute infusions of inotropes and vasoconstrictors may be administered through a peripheral line or intraosseous access, with care taken to avoid and check for extravasation. Central venous access should be obtained as soon as practicable. The choice of adrenaline versus noradrenaline as initial vasoactive can be guided by a combination of clinical signs, central venous saturation and echocardiography.

In children with suspected or demonstrated reduced contractility, adrenaline or dobutamine should be the first-line vasoactive. As a general rule, infants and younger children are most likely to have myocardial dysfunction in septic shock and an inotrope should be favoured over a vasoconstrictor as their initial vasoactive. Dopamine, although still used, may be relatively ineffective in young infants.

Noradrenaline may be used alone if myocardial function is adequate or is added to an inotrope if contractility is poor. Children who continue to have poor perfusion on high-dose noradrenaline warrant a trial of vasopressin; however, a randomised controlled trial in paediatric shock failed to demonstrate any outcome benefit with vasopressin treatment. [23]

There are no trials of inodilators such as milrinone and levosimendan in children with septic shock; given their relatively long half-life and the potential for altered metabolism in organ dysfunction, they should be avoided during the initial resuscitation. They are used as second-line vasoactives in children with septic shock, persistent hypoperfusion and myocardial dysfunction.

Antibiotics

Early and appropriate antibiotic therapy is associated with improved survival and morbidity. [24] Administer antibiotics to patients in whom the cause of shock is not immediately apparent. After appropriate cultures, the selection of antimicrobials is guided by the clinical picture, including any available results from prior cultures, local antibiotic stewardship and prescription practices and resistant organism prevalence. A search for the source or site of infection should be undertaken and it may be necessary to drain collections or remove infected tissue.

Metabolic Support

Give hydrocortisone to shocked patients who are at risk of absolute adrenal insufficiency including recent or ongoing treatment with corticosteroids, known hypothalamic/pituitary/adrenal disease or purpura fulminans. Current adult guidelines suggest the use of hydrocortisone in fluid and vasopressor refractory septic shock.[21] However, data in children suggest no mortality benefit, and corticosteroid use remains controversial.[25,26] Calcium homeostasis is disrupted in septic shock and normal ionised calcium levels should be targeted in children on vasoactive infusions.

Intravenous Immunoglobulin

Intravenous pooled immunoglobulin (IVIG) has the potential to neutralise bacterial toxins and dampen inflammation. It has potential clinical utility in toxic shock syndromes particularly of Streptococcal origin, in children with primary humoral immunodeficiencies and in those with documented low immunoglobulin levels.[27,28] Outside of these potential indications, the routine use of IVIG in children with septic shock is not recommended.

Extracorporeal Membrane Oxygenation

Current paediatric guidelines recommend extracorporeal membrane oxygenation (ECMO) for refractory septic shock or for respiratory failure in acute respiratory distress syndrome associated with sepsis.[22] In refractory paediatric septic shock, there is emerging evidence that central veno-arterial ECMO cannulation via sternotomy is superior to peripheral or neck cannulation, allowing insertion of larger cannulae and consequently higher ECMO flows.[29,30]

Goals of Treatment

The goals of treatment are to reverse the shock state and ensure ongoing adequate organ perfusion. Although clinically useful information, early goal-directed therapy with specific central venous pressure and central venous saturation ($ScvO_2$) targets is no longer recommended.[31-33] Frequent clinical reassessment should focus on normalising vital signs for age, central and peripheral capillary refill <3 seconds, normal mental state, urine output >0.5 mL/kg/h and checking intravenous sites for signs of extravasation.

Table 95.2

Paediatric cardiac drug doses [14]

DRUG	DOSE
Adenosine	0.1 mg/kg (max 3 mg); increase by 0.1 mg/kg/dose to 0.3 mg/kg (max 12 mg)
Alprostadil (PGE $_1$)	10–100 ng/kg/min
Amiodarone	5 mg/kg over 20–60 min, then 5–15 µg/kg/min
Atropine	0.02 mg/kg (max 0.6 mg)
Bicarbonate (10% NaHCO $_3$)	1–2 mL/kg
Dobutamine	2–10 µg/kg/min
Adrenaline	
Bolus	10 µg/kg (0.1 mL/kg 1:10,000)
Infusion	0.05–0.5 µg/kg/min
Anaphylaxis	10 µg/kg (0.01 mL/kg 1:1000) by deep intramuscular injection
Esmolol	25–250 µg/kg/min
Isoproterenol	0.05–0.5 µg/kg/min
Levosimendan	12.5 µg/kg over 10 min, then 0.2 µg/kg/min for 24 h
Metaraminol	
Bolus	0.01 mg/kg
Infusion	0.05–0.5 µg/kg/min
Metoprolol	0.1 mg/kg over 5 min (max 5 mg)

DRUG	DOSE
Milrinone	0.25–0.75 µg/kg/min
Nitric oxide (inhaled)	10–20 parts per million
Noradrenaline	0.05–0.5 µg/kg/min
Sodium nitroprusside	0.5–3 µg/kg/min
Vasopressin	0.02–0.06 U/kg/h

PGE_1, Prostaglandin E_1.

Plasma lactate is a useful marker of paediatric sepsis severity and may have utility in monitoring response to resuscitation.[34, 35] Hyperlactaemia can also be due to ischaemia of the gastrointestinal tract, liver dysfunction or adrenaline infusion.

Central venous oxygen saturation can be used to assess the adequacy of oxygen delivery in the absence of a pulmonary artery catheter.[36] A sample taken from the superior vena cava (SVC) or SVC/RA (right atrium) junction is best; sampling from within the RA may be contaminated by poorly saturated blood from the coronary sinus or by interatrial shunting. In children with structural heart disease and intracardiac mixing, a SaO_2-$ScvO_2$ difference of ≤30% is normal.

Cardiac Disease

Paediatric Heart Failure

Children with heart failure are a diverse group of patients with a heterogeneous group of diseases leading to worsening heart function. Heart failure can be due to primary or secondary myocardial disease, or the effects of congenital heart disease or its treatment (Table 95.3). Whereas coronary artery disease causes most heart failure in adults, the predominant causes of paediatric heart failure and the need for heart transplantation in high-income countries are primary cardiomyopathies and congenital heart disease. [37] Unique to children with large left-to-right shunts, systemic hypoperfusion and pulmonary overcirculation can occur simultaneously. Globally, rheumatic heart disease, nutritional deficiencies and parasitic infections are common. Although rare, almost all children with new onset heart failure present in a state of severe decompensation, and practitioners should be familiar with the recognition and initial stabilisation of the child in acute decompensated heart failure.

Table 95.3

ALCAPA , Anomalous origin of left coronary artery from pulmonary artery; *AP* , aorto-pulmonary; *AVSD* , atrioventricular septal defect; *HLHS* , hypoplastic left heart syndrome; *SVT* , supraventricular tachycardia; *TOF* , tetralogy of Fallot; *VSD* , ventricular septal defect.

Investigations

- Chest X-ray
- ECG
- Echocardiogram
- Further imaging with computed tomography, magnetic resonance imaging and cardiac catheter may be warranted
- Blood gas, electrolytes, full blood count, renal and liver function, coagulation, B-type natriuretic peptide, troponin, viral testing, bacterial testing, inflammatory markers
- Metabolic and genetic testing in certain patients

Treatment

Treat any identified underlying cause for heart failure (sepsis, correctable congenital heart disease, arrhythmias and anaemia). Treatment of specific disorders is outlined in the following sections.

Cardiomyopathy

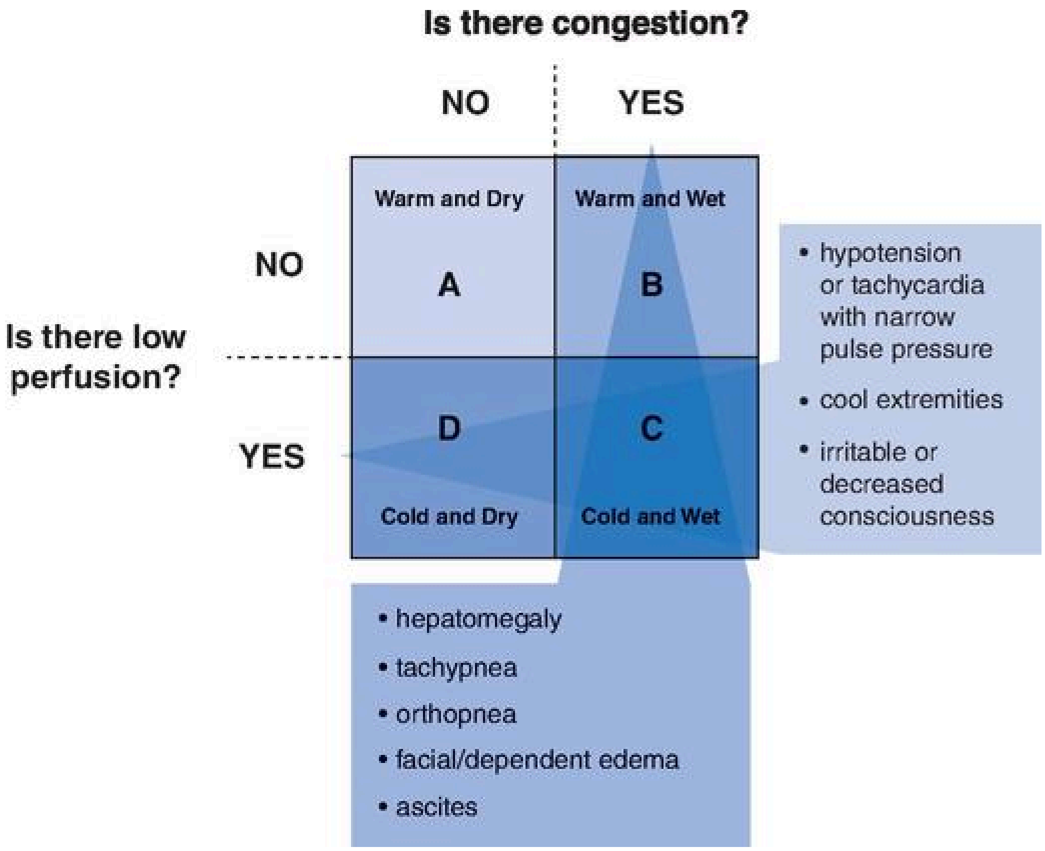
Primary cardiomyopathy is rare in childhood (1.13–1.24 per 100,000 children per year), with the highest incidence in the first year of life. With increasingly sophisticated diagnostic approaches, the cause of cardiomyopathy can be identified in most cases. [38] Dilated and hypertrophic cardiomyopathies account for the majority (~80%) of cases, and there is considerable phenotypic overlap between the different types of cardiomyopathy. The five-year mortality or transplant rate for children with dilated cardiomyopathy is 46%, with younger children and those who are sickest at presentation being at the highest risk. [39]

The clinical presentation is usually one of congestive cardiac failure. Infants present with poor feeding and failure to thrive, along with tachycardia, tachypnoea and sweating. There may be a hyperdynamic precordium and a gallop rhythm. In older children, a careful history will often elicit decreased physical activity in comparison to their peers for many months. The clinical presentation becomes more like that seen in adults, with hepatomegaly, ascites, oedema and poor peripheral perfusion.

Treatment

Compared to adult heart failure, there are relatively few data on which to base treatment of heart failure in children. However, consensus guidelines have been published, providing guidance on management whilst acknowledging the weak evidence base. [40] In line with current adult guidelines, mainstays of chronic paediatric heart failure treatment include diuretic therapy, angiotensin receptor blocker-neprilysin inhibitors, mineralocorticoid receptor antagonists, beta blockers and sodium-glucose transport protein 2 inhibitors. [41]

The sicker child in the ICU with acute decompensated heart failure requires a different approach. The majority of these children require invasive central and arterial access, respiratory support and vasoactive therapy. Ten percent will suffer a cardiac arrest during their ICU admission, and resuscitation drugs should be prepared, particularly if intubating. A useful framework for categorising the severity of illness and approach to resuscitation is provided in Figs. 95.1 and 95.2 .



Is there congestion?
NO
YES
Is there low perfusion?
NO
YES
Warm and Dry
A
Warm and Wet
B
D
Cold and Dry
C
Cold and Wet
• hypotension or tachycardia with narrow pulse pressure
• cool extremities
• irritable or decreased consciousness
• hepatomegaly
• tachypnea
• orthopnea
• facial/dependent edema
• ascites

The decision matrix chart is divided into 4 quadrants, titled Is there congestion question mark on the top and Is there low perfusion question mark on the left. The quadrants are labelled A, B, C, and D. The top row, labelled no, describes warm and dry for quadrant A and warm and wet for quadrant B. The bottom row, labelled yes, describes cold and dry for quadrant D and cold and wet for quadrant C. Two shaded areas highlight medical conditions. One highlights quadrants C and D, listing hypotension or tachycardia with narrow pulse pressure, cool extremities, and irritability or decreased consciousness. Another shaded area highlights quadrants C and B and includes symptoms of hepatomegaly, tachypnea, orthopnea, facial or dependent oedema, and ascites.

Tachycardia
Tachypnoea
Hepatomegaly
Escalation Phase
• High dose inotropes
• Invasive ventilation
• Mechanical circulatory support
OR
Ongoing dependence on ICU therapies
Ward to Outpatient
• Establish chronic heart failure therapies
• Rehabilitation
Transplantation workup

The flowchart illustrates phases of patient management, primarily focusing on cardiac care. It features several rectangular boxes connected by arrows, each describing different phases of treatment and therapy. At the top centre, a box labelled Rescue Phase 24 to 48 Hours lists interventions including inotrope or inodilator, positive pressure ventilation, I V diuretics, and haemoglobin management. To the right, another box labelled escalation phase lists high-dose inotropes, invasive ventilation, and mechanical circulatory support. Below it, a statement suggests ongoing dependence on I C U therapies, leading to a transplantation workup. The left side features the stabilisation phase of 7 to 14 days, including converting to oral diuretics, weaning off vasoactives, initiating A C E I, nutrition, anticoagulation, and diagnosis and prognosis. At the bottom, a box titled Ward to Outpatient focuses on establishing chronic heart failure therapies and rehabilitation. At the entrecenter, a list titled Indicators includes lactate, S c v O 2, renal function, B N P, tachycardia, tachypnea, and hepatomegaly.

FIG. 95.2 Roadmap for management of acute decompensated heart failure in children. Adapted from Kantor PF, Mertens LL. Heart failure in children. Part I: clinical evaluation, diagnostic testing, and initial medical management. *Eur J Pediatr* 2010;169:269–279.

Fluid Management

In children with signs of congestion and adequate perfusion, gentle diuresis can be initiated to reduce ventricular afterload, improve contractility and favour mechanics of ventricular interdependence. In shocked and hypotensive patients, diuretics may not be appropriate during the initial resuscitation. If giving a fluid bolus, aliquots of 5 mL/kg are reasonable but should be aborted if there is no response or the child develops signs of worsening congestion such as an enlarging liver or rales. Correct anaemia to maintain Hb >100 g/L.

Vasoactive Therapy

Milrinone or dobutamine combines the advantages of inotropy and afterload reduction in children who can tolerate vasodilation. More critically unwell children require adrenaline. Despite limited data in children, levosimendan is being used increasingly in paediatric heart failure. It appears capable of increasing cardiac output at minimal metabolic cost and is a potent vasodilator.

Ventilation

Non-invasive and invasive positive-pressure ventilation improve gas exchange, reduce work of breathing and reduce left ventricular afterload.[42] Titrate oxygen to maintain a SaO_2 >95%. The stresses of intubation pose a risk of cardiac arrest in children with severely reduced ventricular function and preparations should be made for resuscitation, including two points of intravenous access, drawn-up resuscitation drugs, rapid access to a backboard and defibrillator and, where available, readiness for extracorporeal cardiopulmonary resuscitation.

Prior to induction, start an adrenaline infusion. Titrate induction drugs to minimise myocardial depression and vasodilation, and recognise that slow circulation can prolong their onset of action. Choose the most experienced intubator available. When manually ventilating, avoid hypoventilation and acidosis but equally avoid breath stacking and high intrathoracic pressures that will reduce preload and increase afterload to the right ventricle.

Mechanical Support

Veno-arterial ECMO (see Chapter 28) or centrifugal ventricular assist device (VAD) can provide excellent short-term mechanical support but are unsuitable for the longer periods necessary for bridging to transplantation. There are very few durable VADs available for such support for the smaller child. The Excor Paediatric VAD ('Berlin Heart') is the most widely used of these, with a range of ventricular chambers down to 10 mL. Successful support to transplantation or recovery can be achieved in 70%–90% of cases, but there is a high risk of infective, bleeding and thrombotic complications. [43] Larger (>30 kg) children can be supported with continuous flow implantable devices designed for adults, which may carry less risk of complications. Development of miniaturised versions of these devices for children is ongoing, but as yet none is ready for clinical use. [44]

An Approach to Congenital Heart Disease

An in-depth discussion of congenital heart disease and its management is beyond the scope of this chapter. What follows is an overview of situations in which the intensivist or emergency physician may encounter congenital heart disease, based loosely on age and mode of presentation.

Newborn With Cyanosis

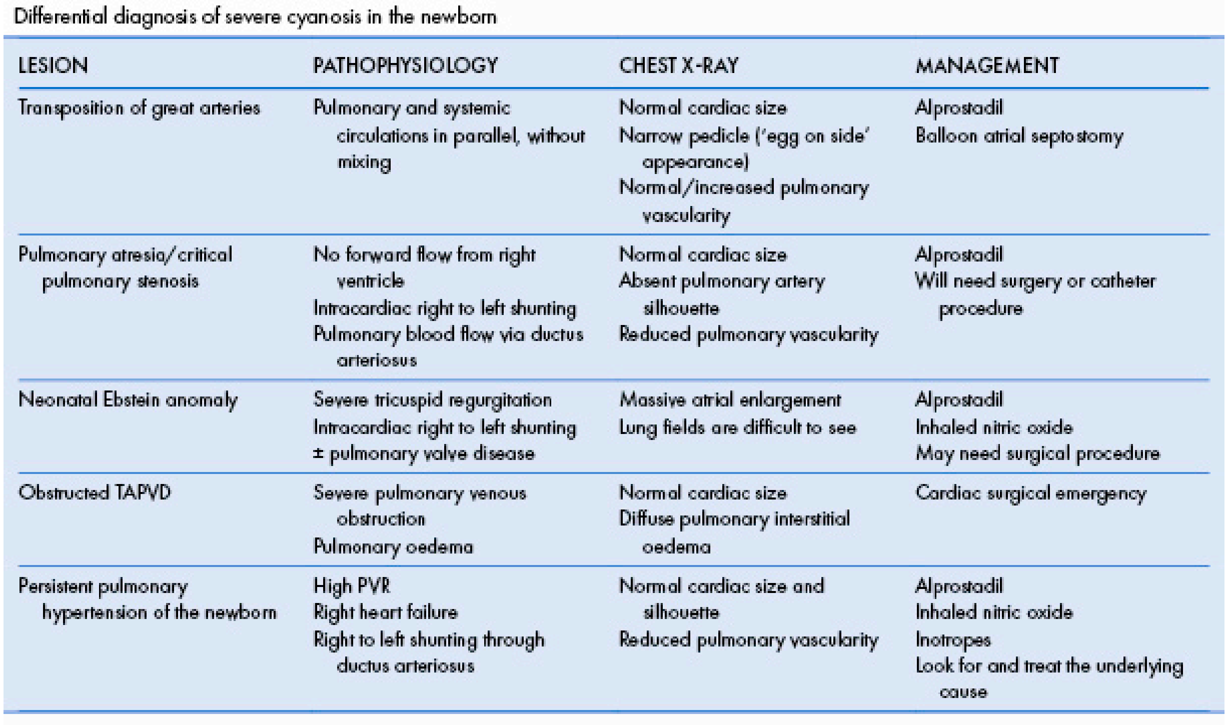
Most cyanosed newborns have respiratory disease and this needs to be treated appropriately. Cyanosis in the absence of respiratory distress is likely to be due to congenital heart disease. Cyanotic heart disease is likely if the PaO_2 does not rise to 150 mm Hg (20 kPa) after the baby has been breathing 100% oxygen for 10 minutes. The presence or absence of a murmur is not particularly helpful; many children with cyanotic heart disease do not have a murmur and murmurs can be heard in many newborn infants. There may be diagnostic clues on examination and chest X-ray, but all such infants need an urgent echocardiogram for definitive diagnosis. [45]

Severe Cyanosis (SaO_2 <70%)

Table 95.4 shows the features of congenital heart lesions presenting with severe cyanosis at birth. These infants must be treated urgently.

1. Intubate and ventilate to reduce oxygen consumption and treat any respiratory disease. Use a high FIO_2 and avoid high pressures that might increase PVR.
2. Start alprostadil (prostaglandin E_1, Prostin) to keep the ductus arteriosus open. There is a risk of exacerbating pulmonary oedema in obstructed total anomalous pulmonary venous drainage, but unless this diagnosis has been made with certainty the ductus should be kept open.
3. Correct metabolic acidosis.
4. Use an inotrope if there is evidence of heart failure (see above).
5. Inhaled nitric oxide may be helpful in persistent pulmonary hypertension of the newborn and severe Ebstein anomaly.
6. Refer for advice and urgent transport to a specialist paediatric cardiac centre. Persistent severe cyanosis may require ECMO support prior to definitive treatment.

Table 95.4



Differential diagnosis of severe cyanosis in the newborn

LESION	PATHOPHYSIOLOGY	CHEST X-RAY	MANAGEMENT
Transposition of great arteries	Pulmonary and systemic circulations in parallel, without mixing	Normal cardiac size Narrow pedicle ('egg on side' appearance) Normal/increased pulmonary vascularity	Alprostadil Balloon atrial septostomy
Pulmonary atresia/critical pulmonary stenosis	No forward flow from right ventricle Intracardiac right to left shunting Pulmonary blood flow via ductus arteriosus	Normal cardiac size Absent pulmonary artery silhouette Reduced pulmonary vascularity	Alprostadil Will need surgery or catheter procedure
Neonatal Ebstein anomaly	Severe tricuspid regurgitation Intracardiac right to left shunting ± pulmonary valve disease	Massive atrial enlargement Lung fields are difficult to see	Alprostadil Inhaled nitric oxide May need surgical procedure
Obstructed TAPVD	Severe pulmonary venous obstruction Pulmonary oedema	Normal cardiac size Diffuse pulmonary interstitial oedema	Cardiac surgical emergency
Persistent pulmonary hypertension of the newborn	High PVR Right heart failure Right to left shunting through ductus arteriosus	Normal cardiac size and silhouette Reduced pulmonary vascularity	Alprostadil Inhaled nitric oxide Inotropes Look for and treat the underlying cause

PVR , Pulmonary vascular resistance; *TAPVD* , total anomalous pulmonary venous drainage.

Less Severe Cyanosis (SaO $_2$ 70%–90%)

Less profound cyanosis is seen in neonates with transposition of the great arteries (TGA) and adequate mixing, milder forms of pulmonary stenosis (including tetralogy of Fallot) and Ebstein anomaly. There is a degree of cyanosis associated with all defects where there is mixing of pulmonary and systemic venous blood (e.g. unobstructed anomalous pulmonary venous drainage, single ventricle lesions). These infants are less sick and cyanosis may be more difficult to detect on physical examination without pulse oximetry. All such children require careful assessment and prompt referral to a paediatric cardiac centre.

Newborn With Cardiac Failure

In lesions that cause obstruction to the left side of the heart (aortic stenosis, coarctation, hypoplastic left heart syndrome) systemic blood flow is provided by the right ventricle through the ductus arteriosus. Patients may not present until the ductus arteriosus begins to close when systemic blood flow diminishes and the left ventricle fails in the face of greatly increased afterload. There is a rapidly deteriorating clinical picture of pallor, cold peripheries and barely palpable pulses. Tachycardia and tachypnoea are universal and there is progressive hepatomegaly, cardiomegaly and pulmonary oedema. This is accompanied by profound metabolic acidosis and oliguria.

Other conditions presenting with cardiovascular collapse in the first two weeks of life are sepsis, inborn errors of metabolism, myocarditis/cardiomyopathy and sustained tachyarrhythmia. These can be difficult to differentiate initially and all neonates presenting in this fashion should be treated with appropriate antibiotics until a definitive diagnosis is made.

Treatment

1. Intubate and ventilate with resuscitation drugs to hand.
2. Sedate and ventilate to reduce oxygen consumption.
3. Start inotropes: adrenaline, milrinone or dobutamine depending on the severity of cardiac dysfunction.
4. Start alprostadil – a high dose (50–100 ng/kg/min) may be needed to reopen the ductus arteriosus.
5. Refer for advice and urgent transport to a paediatric cardiac centre.

Investigations

- Chest X-ray
- Echocardiogram
- ECG
- Blood gas, electrolytes, renal and hepatic function, troponin I
- Full blood count and film examination
- Coagulation
- Blood cultures, viral testing and inflammatory markers

- Metabolic and genetic testing in certain patients.

Cyanosis Beyond the Newborn Period

Infants and young children with unoperated tetralogy of Fallot may present with episodic profound cyanosis associated with crying and agitation. These ‘tet spells’ are mostly due to dynamic obstruction of the right ventricular outflow tract with consequent right to left shunting through the ventricular septal defect (VSD). Administration of oxygen and bringing the child’s knees up tight to the chest will often terminate the spell; possibly by increasing preload and systemic vascular resistance. Intravascular volume expansion may also be helpful. If there is persisting cyanosis, sedation with morphine can be tried. In very resistant spells, either a beta blocker (esmolol) or a peripheral vasoconstrictor (metaraminol) can be used. Inotropes and vasodilators will worsen the cyanosis.

Children with unrepaired or undiagnosed atrial or VSDs (or residual defects following repair) may become cyanosed under conditions of increased PVR, for example during acute respiratory illness. Cyanosis due to progressive pulmonary vascular disease with unrepaired long-standing left-to-right shunt (Eisenmenger’s complex) is increasingly rare.

Certain operations for congenital heart disease leave patients with obligatory intracardiac mixing, producing cyanosis. Pulse oximetry readings in these patients will usually be in the range of 70%–85% (parents will know their child’s usual saturations). These children often have pulmonary blood flow supplied via an aorto-pulmonary shunt (e.g. modified Blalock Taussig [‘BT’] shunt or central shunt).

Two operations redirect systemic venous return directly to the pulmonary artery, bypassing the heart: the Glenn, or bidirectional cavopulmonary connection (SVC to pulmonary artery) and the Fontan (inferior vena cava and SVC to pulmonary artery). Patients with a Glenn remain cyanosed, whereas patients with a Fontan have variable desaturation. In both cases, pulmonary blood flow is extremely sensitive to PVR. If these patients require mechanical ventilation it is important to use low pressures and low rates if possible as positive intrathoracic pressure will impair pulmonary blood flow.

Emergencies and Important Presentations

Dehydration

Dehydration is particularly dangerous in cyanosed patients. These patients often have a high haematocrit and further haemoconcentration places them at risk of thrombosis. Intravenous rehydration should be aggressively pursued in dehydrated children with cyanotic heart disease.

Profound Desaturation

Acute profound desaturation in a patient with shunt-dependent pulmonary blood flow suggests the possibility of shunt blockage and is a life-threatening emergency. An intravenous fluid bolus should be administered (10 mL/kg 0.9% NaCl) and repeated if necessary. Intubation and mechanical ventilation are usually required. Discuss urgently with a paediatric cardiac centre and consider giving heparin (100 U/kg).

Intercurrent Respiratory Illness

Respiratory tract infections are common in childhood and have important effects on children with limited or shunt-dependent pulmonary blood flow. Increased work of breathing and increased PVR will worsen cyanosis. Respiratory failure must be treated on its merits, but the nature of pulmonary blood flow and the potential for increasing PVR must be borne in mind if mechanical ventilation is necessary.

Heart Failure Beyond the Newborn Period

Congenital heart disease-related heart failure beyond the newborn period may be due to the consequences of an unrepaired left-to-right shunt lesion. High pulmonary blood flow places a volume load on the left ventricle. Left ventricular enlargement and increased end-diastolic pressures ensue and the patient presents with tachycardia, tachypnoea, sweating, poor feeding and poor growth. There is often a gallop rhythm and a systolic murmur, and peripheral vasoconstriction leads to cool peripheries. These children respond well to diuretics and ACE inhibitors but may need inotropes and positive-pressure ventilation at presentation. Avoid excess oxygen, which will reduce PVR and exacerbate the left-to-right shunt. Worsening cardiac failure in the first few months of life is often due to the normal fall in haematocrit at this age and will respond to blood transfusion. [46] These children will need repair of the underlying lesion, but this is rarely urgent.

An important lesion to consider in an infant with previously undiagnosed disease is the anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA). These children present with poor growth and episodic inconsolable crying in the first few months of life. There is cardiomegaly and evidence of antero-lateral infarction on ECG. Echo confirms markedly diminished ventricular function, ventricular dilation and mitral regurgitation. This lesion warrants rapid surgical repair.

Heart failure is an important problem in both children and adults with treated congenital heart disease. [47] There are multiple potential causes for systolic or diastolic dysfunction in this population, such as residual shunts, valvular dysfunction, abnormal loading conditions, dysrhythmias and the consequences of previous surgeries. Ischaemic cardiomyopathy occurs rarely, but it can be seen following the repair of coronary artery abnormalities or operations involving manipulation or reimplantation of the coronaries, most notably the arterial switch operation.

Emergencies and Important Presentations

Intercurrent Respiratory Illness

Respiratory tract infections will cause an exacerbation of heart failure in children with congenital heart disease. Increased work of breathing and fever are poorly tolerated and often necessitate hospitalisation. This is most commonly seen in infants with unrepaired left-to-right shunt lesions and viral respiratory tract infections during the winter. It may be difficult to differentiate the effects of respiratory disease from heart failure, but initial attention to the treatment of respiratory failure must be accompanied by careful assessment of the underlying disease.

Disorders of Cardiac Rhythm

Sinus Bradycardia

Sinus bradycardia may appear more dramatic due to the frequent occurrence of sinus arrhythmia in children. Pathological causes of bradycardia include sinus node dysfunction, hypothermia, high intracranial pressure, cervical spinal cord injury, hypothyroidism, drug effects (beta blockers, digoxin, amiodarone and clonidine) and organophosphate poisoning. Sinus bradycardia very rarely needs treatment apart from addressing any underlying cause. Atropine or isoproterenol (isoprenaline) will increase the heart rate if necessary.

Sinus Node Dysfunction

Sinus node dysfunction causes bradycardia, sinus pauses and alternating bradycardia/tachycardia. It is most common following operations for congenital heart disease, particularly those involving extensive atrial surgery, and can occur many years later. Sinus node dysfunction is rare in children with structurally normal hearts. Emergency treatment involves treatment of bradycardia, if symptomatic, and consideration for pacemaker insertion.

Complete Heart Block

Complete heart block is usually congenital in children, with more than 90% being due to the transplacental passage of maternal autoantibodies in autoimmune disease. In later childhood, complete heart block is most likely to be associated with recent cardiac surgery or complex forms of congenital heart disease (congenitally corrected TGA, left atrial isomerism), but may also occur with myocarditis, cardiomyopathy, cardiac transplant rejection and some muscular dystrophies.

Management

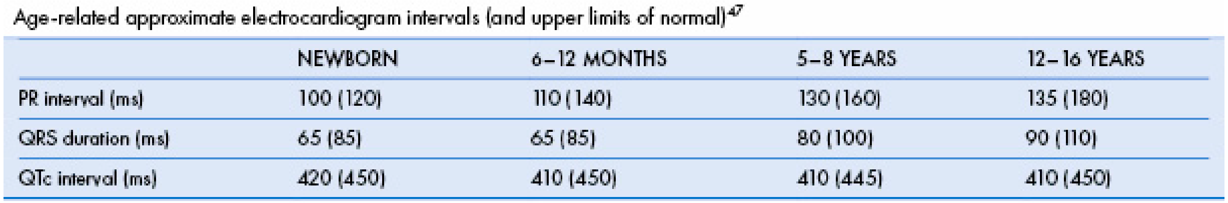
Atropine will increase the ventricular rate and an infusion of isoproterenol will maintain it pending establishment of temporary or permanent cardiac pacing.

Inotropes should be used in patients with poor ventricular function due to long-standing bradycardia or underlying myocardial disease. Transvenous temporary pacing is difficult in small children and external cardiac pacing may be necessary as a resuscitative measure. Asymptomatic patients may still require the insertion of a pacemaker, depending on the cause, ventricular escape rate and myocardial function.

First-Degree Heart Block

A prolonged PR interval (Table 95.5 for normal intervals in different age groups) can be seen in normal children during periods of increased vagal tone. Pathological causes of first-degree block include hypothermia, electrolyte abnormalities, acute rheumatic fever and any of the causes of complete heart block described above.

Table 95.5



Age-related approximate electrocardiogram intervals (and upper limits of normal)[47]

	NEWBORN	6–12 MONTHS	5–8 YEARS	12–16 YEARS
PR interval (ms)	100 (120)	110 (140)	130 (160)	135 (180)
QRS duration (ms)	65 (85)	65 (85)	80 (100)	90 (110)
QTc interval (ms)	420 (450)	410 (450)	410 (445)	410 (450)

All intervals in milliseconds. QTc = corrected QT interval = QT√(heart rate/60).

Second-Degree Heart Block

Isolated Mobitz type I block (Wenckebach) is usually well tolerated. Mobitz type II is more likely to be symptomatic and require a pacemaker. Either form of second-degree atrioventricular (AV) block should be investigated for an underlying cause.

Tachyarrhythmias

Sinus tachycardia is more common than tachyarrhythmia. Underlying causes (fever, pain or agitation, drugs) should be considered and treated. [48]

Supraventricular Tachycardia

Re-entrant supraventricular tachycardia (*SVT)* is common in childhood. [49] Most cases occur in the first few months of life in the absence of congenital heart disease. However, structural heart disease should be ruled out in all cases. The re-entry circuit usually involves the AV node and an accessory conduction pathway. These tachycardias are abrupt in onset and have a relatively fixed rate. In neonates and infants, the accessory pathway is discrete from the AV node and may conduct in either direction (accessory-pathway-mediated SVT). In older children and adults, the alternative conduction route is often within the AV node itself, with two limbs of the node conducting at different frequencies and with different refractory periods (AV node re-entrant tachycardia).

Diagnosis

The ECG shows a narrow complex (see Table 95.5) tachycardia at greater than 200 beats per minute. [50] P-waves are often difficult to discern but occur with a 1:1 ratio to the QRS complexes. P-waves are usually inverted, but morphology and position will depend on the nature of the re-entry circuit.

Treatment

If shocked give:

- oxygen by mask, and sedation
- synchronised cardioversion (1 J/kg).

If stable:

1. *Vagal stimulation:* apply ice water to the entire face for less than 30 seconds, gag, tracheal suction or hold inspiration if ventilated. Carotid massage and eyeball pressure are no longer recommended.

2. *Adenosine rapid intravenous bolus and flush:* give as centrally as possible. If unresponsive increase the dose.
3. *Atrial or transoesophageal overdrive pacing:* may terminate the arrhythmia.
4. *If unsuccessful or the tachycardia reverts after successful termination:* consider beta blockade, amiodarone or digoxin.
5. Do *not* use digoxin or verapamil if there is pre-excitation on the ECG (they both may enhance anterograde conduction in the accessory pathway).
6. Do *not* use verapamil in infants (it can cause shock and cardiac arrest).
7. *Following conversion to sinus rhythm:* check ECG for evidence of pre-excitation and look for structural disease.

Automatic SVTs are caused by an ectopic rapidly firing focus within the atrium or AV conducting tissue. These are unusual in the absence of structural heart disease and are commonly seen following cardiac surgery. Typically, there is variability in the ventricular rate.

Ectopic atrial tachycardia (EAT) has an abnormal P-wave axis on the ECG with normal conduction to ventricles. Junctional ectopic tachycardia (JET) arises at the AV node or high in the bundle of His. There is complete AV dissociation on the ECG, the ventricular rate being greater than the atrial rate.

Treatment is aimed at reducing automaticity with adequate sedation and analgesia and avoiding catecholamines and other chronotropes. Keep serum potassium, calcium and magnesium in the high normal range. Whole-body cooling is useful. Amiodarone can be used in resistant postoperative JET.

Atrial Fibrillation

Atrial fibrillation is rare in children and is usually associated with cardiomyopathy or previous atrial surgery.

Atrial Flutter

Atrial flutter is an atrial re-entrant tachycardia. It can occur in newborns in the absence of structural heart disease but is more common in older patients with congenital heart disease, particularly those who have had surgery involving extensive atrial manipulation. Atrial flutter rates in children are faster than in adults (>400 per minute in newborns). Diagnosis may be evident from the sawtooth baseline pattern of the ECG, but this may not be revealed until adenosine is given, blocking AV conduction. Treat shocked patients as described above for SVT. In the stable patient, atrial or transoesophageal overdrive pacing may terminate the arrhythmia.

Ventricular Arrhythmias

Isolated premature ventricular contractions are common in infants and children with normal hearts. Ventricular arrhythmias are very rare in children (most cases of paediatric cardiac arrest present with severe bradycardia or asystole). Documented ventricular fibrillation or ventricular tachycardia must prompt an exhaustive search for an underlying cause (Box 95.2).

Box 95.2

Causes of ventricular arrhythmias in children

Congenital heart disease (repaired tetralogy of Fallot, aortic stenosis)
Cardiomyopathy
Myocarditis
Ischaemia (coronary abnormalities, Kawasaki disease)
Transplant rejection
Electrolyte abnormalities (hypo/hyperkalaemia, hypocalcaemia)
Drugs (tricyclic antidepressants)
Cardiac channelopathies (long QT syndrome, Brugada syndrome)
Cardiac tumours
Commotio cordis

Emergency treatment of ventricular arrhythmias is described in Chapter 100 .

Neurological emergencies in children

Nitesh Singhal and Michaela Waak

Introduction to neurological and neurosurgical emergencies

Neurological and neurosurgical emergencies combined are the most common life-threatening emergencies in children and often cause significant long-term effects with impacts on the child and family. In resource-rich settings, after the first year of life, the leading cause of death in childhood is injury, particularly traumatic brain injury. There is a range of conditions affecting the brain, spinal cord and peripheral nervous system that require prompt recognition, resuscitation and definitive management. The pathophysiology, clinical features, management and outcome of these emergencies are influenced by several important differences between children, including adolescents and adults. Aetiologies differ as do symptoms and expression of brain injury. One reason is that the maturity of the immune and other systems impacts the primary and secondary brain injury, which often includes activation of inflammatory cascades. Robust outcome data requires longer periods of follow-up, as developmental age and the fact that certain deficits cannot be diagnosed until certain developmental milestones should have been reached, means children often ‘grow into their brain injury’ over time as deficits become apparent.

Pathophysiology of Brain Injuries in Children

Brain injuries are usually caused by a primary event (e.g. trauma, ischaemia, infection or metabolic disturbance), and are frequently accompanied by secondary injuries, including oedema, altered cerebrovascular autoregulation, tissue hypoxia or other cytotoxic mechanisms. Therapy administered after the event will not influence the outcome of the primary injury; however, appropriate resuscitation, treatment and the avoidance of iatrogenic complications may prevent or reduce the impact of secondary injuries. Features of brain injury particular to the paediatric patient are described below.

Cerebral Blood Flow and Metabolism

In children, cerebral blood flow (CBF) changes markedly with age and reaches adult values by 20 years of age. CBF is determined by cerebral perfusion pressure (CPP) divided by cerebral vascular resistance (CVR). Factors which affect CVR include flow-metabolism coupling, arterial carbon dioxide tension, arterial oxygen tension and autoregulation. Intentional manipulation of these factors plays a key role in the management of children with acute brain injury.

CPP is the key to achieving blood flow through the brain; it is the mean arterial pressure (MAP) minus the greater of either the cerebral venous pressure or the intracranial pressure **(** ICP **)** . In healthy children with intact autoregulation, CBF remains constant over a wide range of MAP or CPP. However, in children with acute brain injury and impaired autoregulation, CBF becomes pressure-dependent and directly changes with changes in CPP and other variables. In this patient cohort, one critical management aim is to maintain the optimum CPP by increasing the MAP and decreasing the ICP. The ideal CPP in childhood is not known and likely depends on many factors including age and aetiology of brain injury as well as the phase of the brain injury. The target CPP is usually adjusted for age, taking into consideration the normative values for systolic or mean arterial blood pressure. [1] For example for an adolescent patient the therapy may be directed at maintaining a CPP of 60 mm Hg, whereas for a child aged 5 years, the aim may be to maintain a CPP of 50 mm Hg.

In adults, autoregulation usually maintains a constant CBF between a MAP of 50 to 150 mm Hg; however, the upper limit of the pressure autoregulation curve is lower in neonates with important clinical implications. [1] Since the range of CBF autoregulation for infants is 40–90 mm Hg, [2] even moderate hypotension in young children may severely impede oxygen delivery to the brain while moderate hypertension may result in unacceptable increases in CBF and damage to the blood brain barrier (BBB) and therefore worsening cerebral oedema and raised ICP. Meticulous control of MAP in brain-injured neonates and infants to minimise the risk of cerebral ischaemia and secondary haemorrhage is therefore paramount.

The brain comprises 12% of body weight in infancy compared with 2%–3% in adulthood. Cerebral oxygen and glucose consumption are therefore proportionately greater in childhood and glycogen stores are readily depleted. Hypoglycaemia occurs commonly in severe illnesses such as sepsis; therefore blood glucose should be monitored meticulously and age-appropriate targets set.

Hypovolaemia

Children have small blood volumes and commonly develop hypovolaemia from scalp bleeding or intracranial haemorrhage. For example hypovolaemia will develop in a 5 kg infant (blood volume 400 mL) following blood loss of less than 100 mL. Hypovolaemia should be treated aggressively with fluid boluses of 20 mL/kg to ensure adequate cerebral perfusion.

Relative Growth

A child’s short stature and proportionately large head confer several risks, including isolated head injury following pedestrian accident (their head is at the level of the front of a motor vehicle). The neck muscles are relatively weak and this renders the brain prone to deceleration injury in motor vehicle crashes and in cases of domestic violence. Injury inflicted by shaking an infant by the shoulders snaps the head to and fro leading to compression of brain tissue and rupture of delicate bridging veins.

Bone Development

The bones of the skull in the first year of life are thin with open sutures and fontanelles. Beyond 2 years, the skull sutures close and the cranial vault thickens. In young children there tends to be less bony protection from high-impact trauma, although the nonrigid skull may expand to partially decompress expanding lesions. Therefore symptoms might be protracted and make early diagnosis and management of raised ICP difficult.

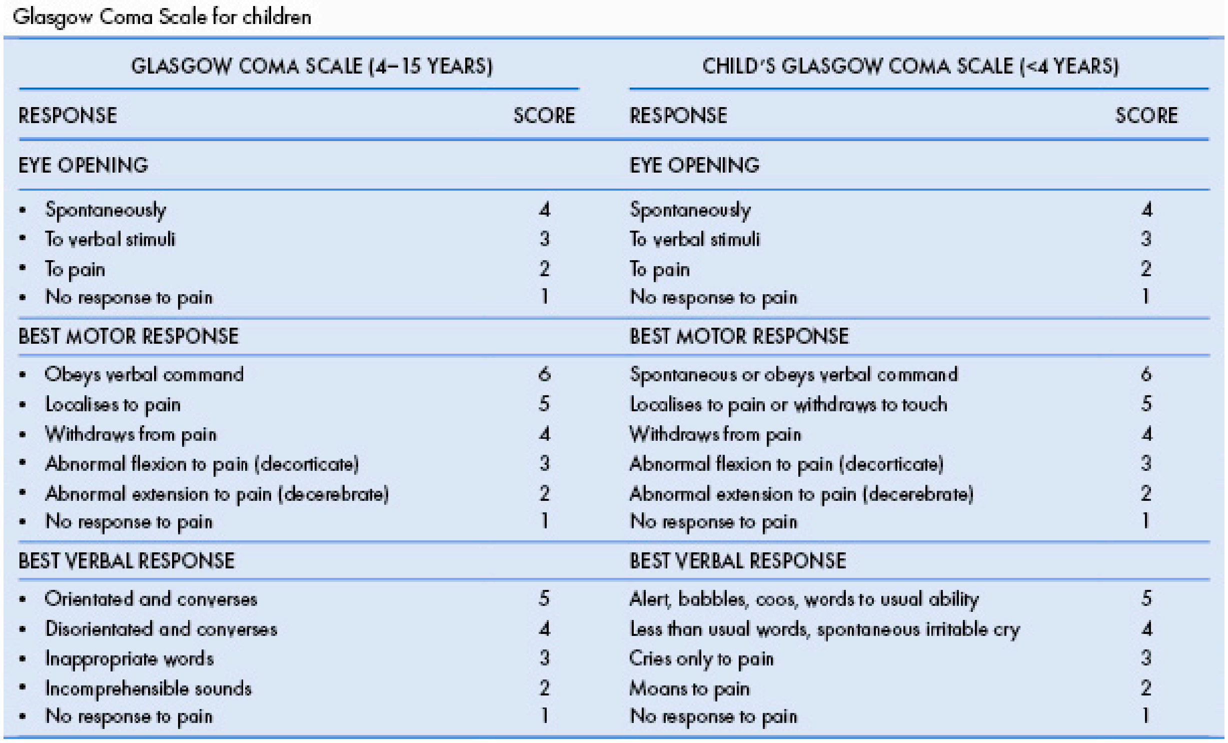
Initial Management

Acute brain injury can present with focal neurological deficits or symptoms typically associated with more global deficits, in particular mild encephalopathy. The purpose of the initial evaluation is to identify and treat acute injuries and prevent secondary injuries. In healthy children, CBF meets cerebral metabolic demand through flow-metabolism coupling. In children with acute brain injury, this is usually impaired, and the aim is to restore this balance by decreasing the metabolic demands and optimising the metabolic supply.

Rapid assessment of the adequacy of airway, breathing and circulation can inform immediate interventions aimed at correcting them. Once venous access is obtained, blood should be collected for routine tests including immediate measurement of venous blood gas including blood glucose, electrolytes and pH. If hypoglycaemia is detected, 1 mL/kg of 25% glucose or 2.5 mL/kg of 10% glucose should be given intravenously as the neurological sequelae of unrecognised hypoglycaemia can be profound. Electrolytes should be corrected and oxygenation, ventilation, BP and pH targets clearly communicated.

Concurrent with the initial assessment and resuscitation, relevant details of the present and past history should be obtained. A detailed neurological and general physical examination should be performed. It is important to accurately document conscious state and degree of encephalopathy so that changes over time, particularly deterioration, can be easily recognised. As the responses of children change with developmental age the Glasgow Coma Scale (GCS) (Table 96.1) as well as the National Institutes of Health Stroke Scale (NIHSS) for acute ischaemic stroke must be modified for paediatric use. Acute neurological emergencies require a very different initial assessment focused on a structured neurological exam, e.g. the NIHSS for acute ischaemic stroke. [3, 4] Acute encephalopathy is in fact not associated with raised ICP but reflects an initially often focal neurological deficit that can rapidly progress to a more global deficit if not recognised and managed in a timely fashion. [5, 6]

Table 96.1



Glasgow Coma Scale for children

GLASGOW COMA SCALE (4–15 YEARS)		CHILD'S GLASGOW COMA SCALE (<4 YEARS)	
RESPONSE	SCORE	RESPONSE	SCORE
EYE OPENING		EYE OPENING	
• Spontaneously	4	Spontaneously	4
• To verbal stimuli	3	To verbal stimuli	3
• To pain	2	To pain	2
• No response to pain	1	No response to pain	1
BEST MOTOR RESPONSE		BEST MOTOR RESPONSE	
• Obeys verbal command	6	Spontaneous or obeys verbal command	6
• Localises to pain	5	Localises to pain or withdraws to touch	5
• Withdraws from pain	4	Withdraws from pain	4
• Abnormal flexion to pain (decorticate)	3	Abnormal flexion to pain (decorticate)	3
• Abnormal extension to pain (decerebrate)	2	Abnormal extension to pain (decerebrate)	2
• No response to pain	1	No response to pain	1
BEST VERBAL RESPONSE		BEST VERBAL RESPONSE	
• Orientated and converses	5	Alert, babbles, coos, words to usual ability	5
• Disorientated and converses	4	Less than usual words, spontaneous irritable cry	4
• Inappropriate words	3	Cries only to pain	3
• Incomprehensible sounds	2	Moans to pain	2
• No response to pain	1	No response to pain	1

Stabilising Airway and Breathing

Indications for providing airway and/or breathing support in an encephalopathic or comatose child are:

- upper airway obstruction or loss of airway reflexes
- apnoea or respiratory failure
- rapidly worsening encephalopathy or coma (if concerned that any of the other criteria will be met rapidly)
- GCS <9
- signs of progressive elevation of ICP (i.e. progressive deterioration of conscious level, bradycardia, hypertension, abnormal pupillary light reflexes and 'false localising' signs).[6]

So-called 'false localising signs' in the context of suspected raised ICP typically are bilateral ptosis, impaired upgaze or extension to pain. Changes in blood pressure, pulse and respiratory pattern are typically late signs of raised ICP.[7]

In children with suspected cervical spine injury, intubation should always be performed with manual axial in-line stabilisation. In intubated patients without signs of raised ICP, the goals of oxygenation and ventilation are to achieve oxygen saturations (SpO_2) ≥ 95% and normocapnia.

Maintaining adequate Circulation

Patients with acute brain injury should have close monitoring of their haemodynamic status. Intravascular access should be obtained early, and blood pressure initially maintained with isotonic fluids and vasoactive medications as needed. Hypotension should be managed aggressively as any episode of hypotension further exacerbates secondary brain injury. MAP targets would be high normal for age (e.g. > 95th centile).[1]

Sedation and Analgesia

Adequate analgesia, supplemented by sedation as required, is crucial to prevent increased cerebral oxygen demand, for example, driven by pain, agitation and coughing. Muscle relaxants may be necessary to facilitate ventilation and prevent shivering; however, their use precludes serial neurological assessment, and therefore if long-acting muscle relaxants are continued, multimodal monitoring to enable recognition of changes in neurological state is advisable.

Targeted Temperature Management

While there is no current evidence to support the routine use of therapeutic hypothermia as a neuroprotective measure in traumatic brain injury or post-cardiac arrest patients, there is evidence that any fever further exacerbates acute brain injury. Following cardiac arrest children are usually hypothermic. Fever commonly develops during the subsequent hours and is associated with worse outcomes. [8] Therefore in patients with acute brain injury the goal is to actively and pre-emptively target normothermia. [9-13]

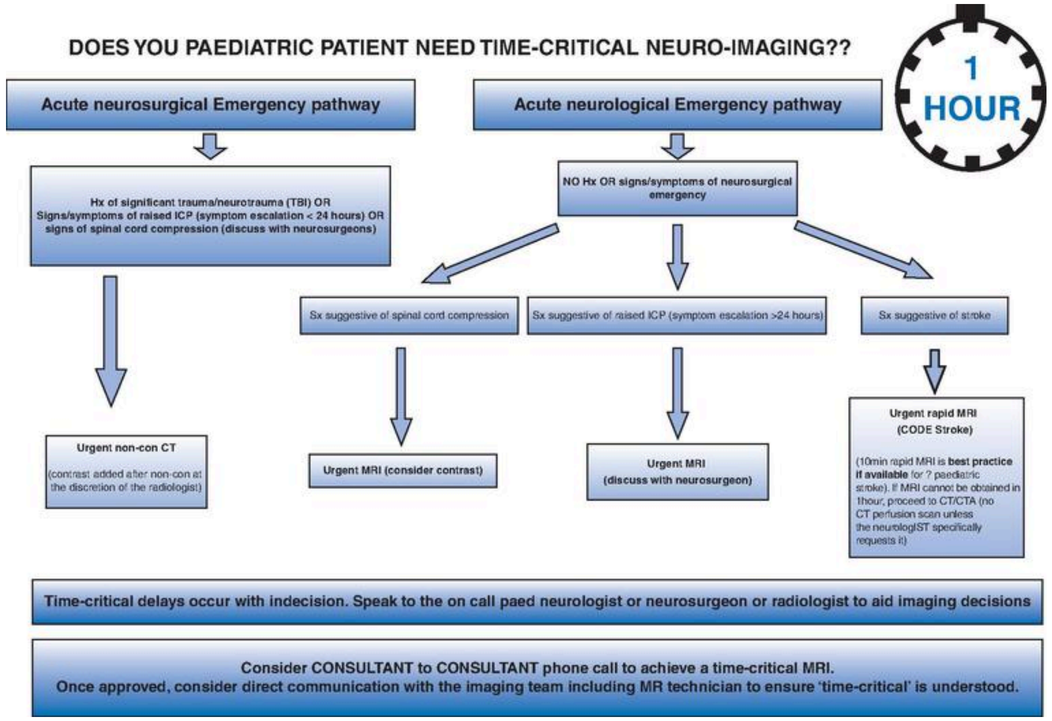
Intracranial Hypertension

Raised ICP should be considered in any case of rapidly progressive deterioration in conscious level (assessed using GCS). If critical intracranial hypertension is suspected clinically, management should include hyperosmolar therapy such as hypertonic saline given as 3–5 mL/kg of 3% solution (0.5 mmol/mL) or intravenous mannitol 0.25–0.5 g/kg. If mannitol is administered it is advisable to anticipate osmotic diuresis and changes in fluid state potentially impacting BP. [14] Hyperventilation is a short-term manoeuvre and, aimed at facilitating neurosurgical intervention. If used during the early resuscitation phase, a gradual return to a low–normal $PaCO_2$ should be the aim. This is best achieved with end-tidal CO_2 and ICP monitoring calibrated to a $PaCO_2$. Particular attention should be paid to restoring intravascular volume and maintaining an adequate CPP. Simultaneously maximal surgical interventions should be initiated. [15]

INVESTIGATIONS

Neuroimaging

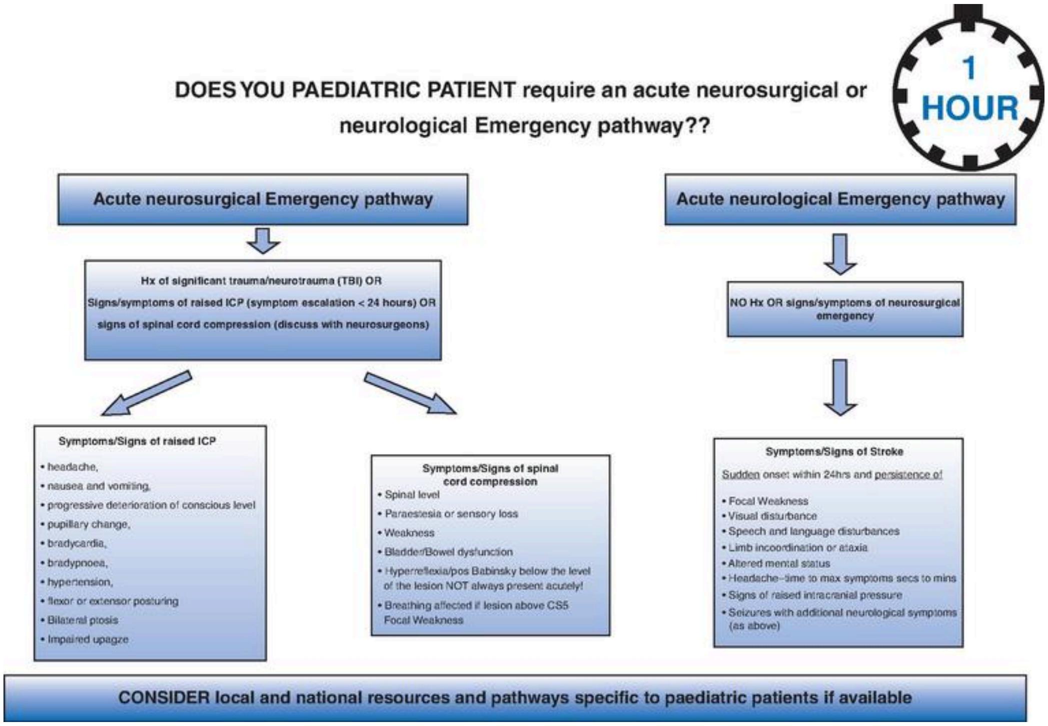
Acute neuroimaging is often the most time-critical initial investigation to establish aetiology as well as diagnose the presence and severity of the suspected brain injury in children presenting with signs and symptoms of a ‘brain attack’.[16,17] Acute neurological emergencies can present with an acute onset focal neurological deficit (motor, speech, vision and others), headaches or seizures with or without other symptoms or altered level of consciousness. Emergency paediatric stroke protocols have been developed in the past 10 years in some paediatric and mixed centres to ensure that time-critical neuroimaging can occur. In this instance, a 5–7 minute rapid sequence MRI/MR-A (±MR perfusion) is best practice.[18] If acute signs of raised ICP are present, or access to an MRI brain is not available the initial neuroimaging modality of choice is a cranial computerised tomography (CT) scan, often with contrast (CT-A) and sometimes including perfusion imaging if acute ischaemic stroke is suspected. Ultrasound of the brain can be indicated in some instances when neonates and infants still have an open anterior fontanelle (Figs. 96.1 and 96.2).



DOES YOU PAEDIATRIC PATIENT NEED TIME-CRITICAL NEURO-IMAGING??
1 HOUR
Acute neurosurgical Emergency pathway
Acute neurological Emergency pathway
Hx of significant trauma/neurotrauma (TBI) OR Signs/symptoms of raised ICP (symptom escalation < 24 hours) OR signs of spinal cord compression (discuss with neurosurgeons)
NO Hx OR signs/symptoms of neurosurgical emergency
Sx suggestive of spinal cord compression
Sx suggestive of raised ICP (symptom escalation >24 hours)
Sx suggestive of stroke
Urgent non-con CT
(contrast added after non-con at the discretion of the radiologist)
Urgent MRI (consider contrast)
Urgent MRI
(discuss with neurosurgeon)
Urgent rapid MRI
(CODE Stroke)
(10min rapid MRI is best practice if available for ? paediatric stroke). If MRI cannot be obtained in 1hour, proceed to CT/CTA (no CT perfusion scan unless the neurologIST specifically requests it)
Time-critical delays occur with indecision. Speak to the on call paed neurologist or neurosurgeon or radiologist to aid imaging decisions
Consider CONSULTANT to CONSULTANT phone call to achieve a time-critical MRI.
Once approved, consider direct communication with the imaging team including MR technician to ensure 'time-critical' is understood.

The flowchart is designed to aid in determining the need for time-critical neuro viewing for paediatric patients. The title at the top reads, Does your paediatric patient need time-critical neuro viewing question mark question mark below. The chart is divided into two main pathways, including the acute neurosurgical emergency pathway and the acute neurological emergency pathway, each with its own set of criteria and subsequent actions. Under the first pathway, significant trauma or neurotrauma, raised intracranial pressure symptoms, or spinal cord compression signs lead to urgent non-contrast C T. The second pathway, for non-neurosurgical emergencies, directs toward M R I based on symptoms of spinal cord compression, raised intracranial pressure, or stroke signs. To the right, a clock illustration with 1 hour emphasises urgency. Below the pathways, advisory notes stress the importance of timely decisions and proper consultation for best outcomes. Notes below state that Time-critical delays occur with indecision. Speak to the on-call paed neurologist or neurosurgeon, or radiologist to aid imaging decisions. Consider a consultant-to-consultant phone call to achieve a time-critical M R I.

FIG. 96.1 Approach to neuroimaging for patients with acute neurological emergency.



DOES YOU PAEDIATRIC PATIENT require an acute neurosurgical or neurological Emergency pathway??
1 HOUR
Acute neurosurgical Emergency pathway
Hx of significant trauma/neurotrauma (TBI) OR
Signs/symptoms of raised ICP (symptom escalation < 24 hours) OR
signs of spinal cord compression (discuss with neurosurgeons)
Symptoms/Signs of raised ICP
• headache,
• nausea and vomiting,
• progressive deterioration of conscious level
• pupillary change,

• flexor or extensor posturing
• Bilateral ptosis
• Impaired upagze
Symptoms/Signs of spinal cord compression
• Spinal level
• Paraestesia or sensory loss
• Weakness
• Bladder/Bowel dysfunction
• Hyperreflexia/pos Babinsky below the level of the lesion NOT always present acutely!
• Breathing affected if lesion above CS5 Focal Weakness
Acute neurological Emergency pathway
NO Hx OR signs/symptoms of neurosurgical emergency
Symptoms/Signs of Stroke
Sudden onset within 24hrs and persistence of
• Focal Weakness
• Visual disturbance
• Speech and language disturbances
• Limb incoordination or ataxia
• Altered mental status
• Headache–time to max symptoms secs to mins
• Signs of raised intracranial pressure
• Seizures with additional neurological symptoms (as above)
CONSIDER local and national resources and pathways specific to paediatric patients if available

The flowchart is designed to determine if a paediatric patient requires an acute neurosurgical or neurological emergency pathway. Across the top is the main question such that does your paediatric patient require an acute neurosurgical or neurological Emergency pathway question mark question mark. On the right, there is a clock icon representing 1 hour. Below the main question, two pathways are presented, each in a box, including the acute neurosurgical emergency pathway on the left and the acute neurological emergency pathway on the right. The neurosurgical pathway leads to a box explaining criteria, including significant trauma or neurotrauma and symptoms of raised intracranial pressure or spinal cord compression, with further symptoms listed below in smaller boxes. These include headaches, nausea, and specific motor symptoms. The neurological pathway states no H x O R signs or symptoms of neurosurgical emergency and lists symptoms of stroke, including sudden onset, weakness, visual disturbance, and ataxia. At the bottom, there is a directive to consider local and national resources and pathways specific to paediatric patients if available.

FIG. 96.2 History signs and symptoms triggering time-critical imaging pathways.

Lumbar Puncture

Lumbar puncture (LP) should be performed when there is reasonable suspicion of meningitis or encephalitis. The risks and contraindications to LP are discussed under bacterial meningitis.

Additional Investigations

These include arterial blood gas analysis, serum electrolytes, glucose, urea, creatinine, liver function tests, serum ammonia, serum and cerebrospinal fluid (CSF) microscopy and culture, lactate and pyruvate, oligoclonal bands, neopterin and urine analysis. Appropriate screening of blood and urine will exclude common poisons and drug intoxications. Depending on the level of suspicion, full septic screen and investigations, or endocrine or metabolic tests may be performed.

Specific Treatments

The aetiology, often initially suspected based on clinical signs and results of investigations, generally guides treatment. More fundamentally, symptomatic management, until aetiology can be established, and specific treatments added, initially prevails. Hypoglycaemia, if present, requires rapid correction and prevention. Appropriate glucose-containing intravenous fluid should be commenced with regular blood glucose monitoring. As a guiding principle, it is rare to encounter hypoglycaemia in an infant or child if 5 mg/kg/min of glucose is provided.

Undiagnosed Coma

An ordered approach to diagnosis and treatment is required for a child with a depressed conscious state of unknown origin. This approach must consider common life-threatening and rare treatable diseases (Box 96.1).

Box 96.1

Causes of coma in children

AVM , Arteriovenous malformations.

Status Epilepticus

Convulsive (or electroclinical) status epilepticus (CSE) is usually defined as uninterrupted seizures lasting 5 min or longer OR recurrent seizures totalling 12 minutes in any 1 hour period (hourly seizure burden ≥ 20%) with clinical manifestations.[19] According to the latest statement of the International League against Epilepsy, timepoint one (t1) is considered to be the 5-minute mark, given most seizures lasting 5 minutes will not self-terminate and require treatment.[20] The goal is to avoid reaching timepoint two (t2), originally hypothesised to be 30 minutes, where a clinical or sub-clinical seizure causes independent secondary brain injury. Given recent developments in the recognition and management of the patient cohort diagnosed with new onset refractory status (NORSE), distinction between sub-clinical and clinical seizures when it comes to treatment decisions has become less significant. ***Refractory SE*** refers to clinical or EEG seizures lasting longer than 60 minutes despite treatment with at least one first-line and one second-line anti-seizure medication (ASM); ***Super-refractory SE*** refers to refractory CSE that continues or recurs 24 hours or more after the onset of general anaesthesia administered to control the CSE. [20]

Common causes of CSE in children are:

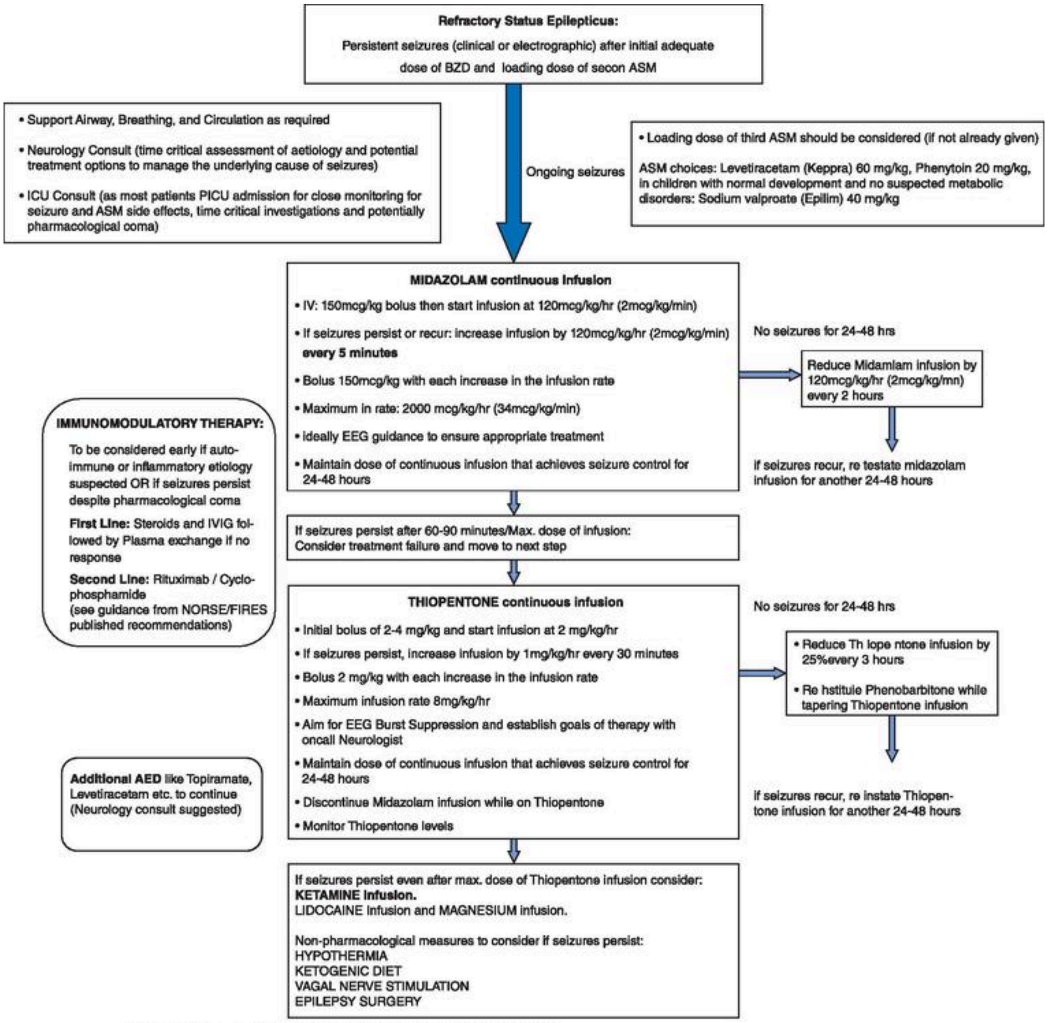
- epilepsy associated with the first presentation, anti-seizure medication (ASM) withdrawal or inter-current illness
- CNS infection (e.g. meningitis or encephalitis)
- inflammatory disorders (including autoimmune encephalitis)
- metabolic disturbance (e.g. hypoglycaemia, hyponatraemia and hypocalcaemia)
- trauma, including inflicted injury
- genetic disorders (e.g. Dravet syndrome)
- posterior reversible encephalopathy syndrome (PRESS).

Pathophysiology

Physiological changes during the compensated phase include tachycardia, hypertension, increased catecholamine release and increased cardiac output. Changes within the brain include increased CBF and increased cerebral metabolic rate. During the decompensated phase there may be falling blood pressure and cardiac output, hypoglycaemia, hypoxaemia, acidosis, electrolyte disturbance and rhabdomyolysis. The cerebral physiology is characterised by failing autoregulation and reduced CBF, and oxygen and glucose utilisation. The exact mechanisms of secondary brain injury remain largely unstudied but include activation of the inflammatory and cytokine cascades. [20] Glutamate accumulation and stimulation of *N*-methyl-d-aspartate receptors (NMDAR) lead to an influx of intracellular calcium, which triggers a number of cytotoxic events and ultimately cell death. [21]

Management

It is crucial to manage seizures lasting more than 5 minutes as a neurological emergency to avoid metabolic and ischaemic neuronal damage. Hypoglycaemia as well as other reversible causes of seizures including electrolyte imbalance should be detected and managed as a priority (Fig. 96.3).



Refractory Status Epilepticus:

Persistent seizures (clinical or electrographic) after initial adequate dose of BZD and loading dose of secon ASM

- Support Airway, Breathing, and Circulation as required
- Neurology Consult (time critical assessment of aetiology and potential treatment options to manage the underlying cause of seizures)
- ICU Consult (as most patients PICU admission for close monitoring for seizure and ASM side effects, time critical investigations and potentially pharmacological coma)

Ongoing seizures

- Loading dose of third ASM should be considered (if not already given)

ASM choices: Levetiracetam (Keppra) 60 mg/kg, Phenytoin 20 mg/kg, in children with normal development and no suspected metabolic disorders: Sodium valproate (Epilim) 40 mg/kg

MIDAZOLAM continuous Infusion

- IV: 150mcg/kg bolus then start infusion at 120mcg/kg/hr (2mcg/kg/min)
- If seizures persist or recur: increase infusion by 120mcg/kg/hr (2mcg/kg/min) **every 5 minutes**
- Bolus 150mcg/kg with each increase in the infusion rate
- Maximum in rate: 2000 mcg/kg/hr (34mcg/kg/min)
- ideally EEG guidance to ensure appropriate treatment
- Maintain dose of continuous infusion that achieves seizure control for 24-48 hours

No seizures for 24-48 hrs

Reduce Midamlam infusion by 120mcg/kg/hr (2mcg/kg/mn) every 2 hours

If seizures recur, re testate midazolam infusion for another 24-48 hours

IMMUNOMODULATORY THERAPY:

To be considered early if auto-immune or inflammatory etiology suspected OR if seizures persist despite pharmacological coma

First Line: Steroids and IVIG followed by Plasma exchange if no response

Second Line: Rituximab / Cyclophosphamide (see guidance from NORSE/FIRES published recommendations)

If seizures persist after 60-90 minutes/Max. dose of infusion: Consider treatment failure and move to next step

THIOPENTONE continuous infusion

- Initial bolus of 2-4 mg/kg and start infusion at 2 mg/kg/hr
- If seizures persist, increase infusion by 1mg/kg/hr every 30 minutes
- Bolus 2 mg/kg with each increase in the infusion rate
- Maximum infusion rate 8mg/kg/hr
- Aim for EEG Burst Suppression and establish goals of therapy with oncall Neurologist
- Maintain dose of continuous infusion that achieves seizure control for 24-48 hours
- Discontinue Midazolam infusion while on Thiopentone
- Monitor Thiopentone levels

No seizures for 24-48 hrs

- Reduce Th lope ntone infusion by 25%every 3 hours
- Re hstitule Phenobarbitone while tapering Thiopentone infusion

If seizures recur, re instate Thiopentone infusion for another 24-48 hours

Additional AED like Topiramate, Levetiracetam etc. to continue (Neurology consult suggested)

If seizures persist even after max. dose of Thiopentone infusion consider:
KETAMINE Infusion.
LIDOCAINE Infusion and MAGNESIUM infusion.

Non-pharmacological measures to consider if seizures persist:
HYPOTHERMIA
KETOGENIC DIET
VAGAL NERVE STIMULATION
EPILEPSY SURGERY

Footnote: BZD = benzodiazepame, ASM = anti seizure medication

The flowchart is titled Refractory Status Epilepticus. It outlines a step-by-step process for treating persistent seizures despite adequate doses of benzodiazepine and second-line antiseizure medication. The chart includes various components within outlined boxes, arrows indicating process flow, and bulleted lists for specific options. The main sections cover continuous infusions of midazolam and thiopentone, including dosage and adjustments. There are additional sections for immunomodulatory therapy, third A S M loading dose considerations, and actions if initial treatments fail.

Annotations provide alternatives and next steps, emphasising seizure control duration.

FIG. 96.3 Refractory status epilepticus management.

First-Line Therapy (5–20 minutes)

Benzodiazepines remain the first-line ASM for stopping seizures that do not terminate spontaneously within 5 minutes.[20,22] The efficacy of benzodiazepines is reduced if administration is delayed. First-line therapy administered pre-hospital either by the parents, care providers or paramedics is crucial; midazolam can be administered via the buccal, intranasal or intramuscular route, lorazepam via the sublingual route and diazepam via the rectal route. Buccal midazolam is more effective and easier and more socially acceptable to administer than rectal diazepam.[20] Once intravenous access is available lorazepam is usually considered the drug of choice because, compared with diazepam, it is at least as effective, is safer and has a longer duration of action.[20,22] If a seizure has not responded to two doses of benzodiazepine given within a reasonably short timeframe from the start of the seizure, a second-line ASM should be administered. If a benzodiazepine has been administered pre-hospital then only one further dose should be administered in the emergency department, and there should be no delays to administration of second-line ASMs.

Second-Line Therapy (20–40 minutes)

A recent RCT (which included adults and children) provided a basis for an updated network analysis-based ranking of second-line ASMs.[23,24] Based on efficacy outcomes (CSE cessation within 1 h from drug administration and seizure freedom at 24 h), as well as safety outcomes (respiratory depression and hypotension) in the clinical practice framework provided by the American Epilepsy Society[22] recommendations, were summarised regarding the second-line ASMs: sodium valproate (20–40 mg/kg), phenytoin (20 mg/kg), fosphenytoin (20 mg(PE)/Kg), lacosamide (400 mg) and levetiracetam (20–60 mg/kg). Sodium valproate use is restricted to children over 2 years of age with no symptoms, namely developmental delay, mitochondrial or other metabolic disorders to avoid potentially life-threatening complications. All ASMs performed equally regarding the occurrence of CSE cessation, seizure freedom at 24 hours, respiratory depression and hypotension. A secondary analysis showed that valproate was best in the achievement of CSE control and seizure freedom, and low likelihood of respiratory depression; lacosamide had the lowest probability of hypotension. [24] Special consideration is required in neonates, were high-grade evidence regarding effectiveness and safety of second-line ASMs is lacking.

Third-Line Therapy (40–60 minutes)

There is no clear evidence to guide ASM and anaesthetic agent choice in the third therapy phase. Choices include administration of second-line therapy not already administered while preparing for the safe administration of anaesthetic doses of thiopental, midazolam, phenobarbital or propofol. This should ideally occur with continuous EEG monitoring to guide ongoing management and avoid administration of unnecessary agents and limit potential side effects of treatment. [25]

Refractory and Super-refractory status epilepticus management

If CSE continues for longer than 40–60 minutes despite the administration of two or at most three different anti-epileptic drugs (AEDs), induction of intravenous anaesthesia should occur followed by intubation and ventilation and admission to intensive care. Thiopentone 2–5 mg/kg slowly IV then 1–5 mg/kg per hour by continuous infusion into a central vein can be given. Thiopentone necessitates endotracheal intubation and mechanical ventilation, and possibly inotropic drugs to counter its hypotensive effects. Continuous EEG monitoring is recommended with a target end-point of burst suppression. If breakthrough seizures occur, repeating bolus doses of 1–2 mg/kg should be administered. If dosing is titrated by adjusting the infusion rate without repeat bolus dosing, unnecessary delay in achieving the therapeutic goal will occur. Blood concentrations need to be monitored during prolonged use. Thiopentone infusions are associated with significant risks of hypotension, infection and ileus. Midazolam infusion has been used as an alternative to thiopentone. After a bolus of 0.2 mg/kg (200 microgram/kg, maximum 10 mg) an infusion is commenced at 0.1 mg/kg per hour (100 microgram/kg/h). If seizures continue or recur, the bolus dose is repeated every 5 minutes and the infusion is increased up to 2 mg/kg per hour (2000 microgram/kg/h). [26] High doses necessitate mechanical ventilation for respiratory depression; however, lower doses are effective at controlling CSE in some cases without the need for ventilation. There are also small case series describing the use of ketamine to control refractory CSE in children with requirement for ventilation. [27]

General anaesthesia is not without risk, but is highly effective at controlling CSE, and can provide time to adjust the dose and stabilise the levels of other AEDs.

It is crucial to consider therapy directed at the suspected aetiology, namely high-dose methylprednisolone and other immunomodulation as recommended when autoimmune encephalitis or febrile infection-related epilepsy syndrome (FIRES) is suspected. [28]

Outcome

The outcome of CSE is dependent on the aetiology. Neurologically normal children in whom CSE is precipitated by fever, not secondary to a significant infection or inflammatory process, are considered to have a good prognosis with mortality reported between 0% and 2%. [29] The incidence of neurological deficits or cognitive impairment in this group is mainly related to mesial temporal sclerosis and can be significant. In acute symptomatic CSE (where CSE is a symptom of an acute neurological process such as infection, inflammation, brain injury or trauma) mortality is 12%–16% and the incidence of new neurological dysfunction is more than 20%. [30] Recent evidence suggests that a seizure burden of more than 20% (> 12 minutes of seizure in a 1-hour EEG recording) contributes significantly to neurological sequelae. [31]

Encephalitis and Meningitis

Bacterial Meningitis

Pathophysiology

Bacterial meningitis usually occurs following haematogenous spread of organisms carried in the nasopharynx. Common bacteria causing meningitis in children are *Streptococcus pneumoniae* , *Neisseria meningitidis* and *Haemophilus influenzae* type b (Hib). Group B *Streptococcus* , *Escherichia coli* and *Listeria monocytogenes* are most common in neonatal meningitis.

Initial cerebral hyperaemia can be followed by cerebral ischaemia, secondary to vasculitis of vessels traversing the sub-arachnoid space, vasospasm or sagittal sinus thrombosis. Cerebral oedema is relatively common in meningitis and is caused by a combination of vasogenic, cytotoxic and hydrostatic factors. If cerebral oedema is severe, raised ICP and impaired cerebral perfusion can occur, leading to global cerebral ischaemia.

Clinical Features

Typical features of meningitis in children are fever, headache, photophobia, neck stiffness and vomiting. The history may extend over several days; however, in fulminant cases, the time from first symptom to coma and death may only be a few hours. [32] Neonates and young infants can present with generalised signs of illness including lethargy, poor feeding and pallor. Generalised or focal convulsions, or apnoea may be the presenting clinical symptoms. Tuberculous meningitis usually presents with a more insidious onset of symptoms and may be associated with focal neurological signs.

During the early phase, meningitis may be associated with septic shock and disseminated intravascular coagulation. Fluid and electrolyte abnormalities are relatively common, particularly hyponatraemia and hypoglycaemia. Focal and generalised seizures are also relatively common and may progress to status epilepticus. During the recovery phase, subdural effusions or hydrocephalus may occur.

Investigations

LP for CSF microscopy, culture and polymerase chain reaction (PCR) testing is required for definitive diagnosis of BM, and to guide antibiotic therapy. Although an LP can be performed safely in the majority of children with bacterial meningitis, it may precipitate brainstem herniation if raised ICP is present. [33] Identifying children at risk of this complication is difficult; however, it is generally recommended that empirical antibiotic therapy be commenced and LP deferred if any of the following clinical features are present: depressed conscious state, decorticate or decerebrate posturing, focal neurological signs or other signs of raised ICP. A normal CT scan does not exclude the possibility of elevated ICP. [33] Therefore the decision to defer an LP should be based on clinical rather than radiological signs. In addition to signs of increased ICP, other indications for deferring the LP include cardiorespiratory instability and severe coagulopathy. If LP is deferred, alternative methods of establishing a bacterial diagnosis include blood culture and PCR testing of blood. [34]

Management

Resuscitation

Severely ill patients require rapid resuscitation. Comatose patients require intubation and ventilation to prevent airway obstruction and hypoventilation. Hypovolaemia should be treated rapidly with boluses of intravenous fluid. Patients with septic shock will also require vasopressor support.

Cerebral Resuscitation

Optimising cerebral oxygen delivery, controlling ICP and preventing cerebral metabolic stress are important. The role of ICP monitoring is controversial. In a randomised controlled paediatric trial of CPP vs ICP targeted therapy in meningitis patients with raised ICP, CPP targeted therapy was superior in reducing mortality and morbidity. [35]

Antibiotic Therapy

Empirical broad-spectrum antibiotics should be selected based on likely pathogens and local resistance patterns. Commonly, protocols recommend ampicillin plus cefotaxime for the first 3 months of life and to use a third-generation cephalosporin (cefotaxime or ceftriaxone) after 3 months of age. [36] In regions where penicillin- and cephalosporin-resistant *Pneumococcus* occurs, vancomycin should be added initially. When cephalosporin-resistant *Pneumococcus* is found to be the causative organism in meningitis, both a third-generation cephalosporin and vancomycin should be continued as vancomycin penetrates into CSF poorly and therefore should not be used as a single agent. The addition of rifampicin should be considered. [36]

Adjuvant Therapy

If dexamethasone is used as adjuvant therapy it should be used only for children over 3 months of age and ideally be given before the first dose of antibiotics and continued for 4 days (0.15 mg/kg 6 hourly). [37] There is evidence that dexamethasone reduces the incidence of neurological sequelae and sensorineural deafness; however, the beneficial effects are greatest in Hib meningitis *(Haemophilus influenzae)* . [38] Current recommendations support the use of dexamethasone prior to or at the time of the first doses of antibiotics for children older than 3 months of age with BM. [37], [38]

Intravenous Fluid Therapy

There is consensus that hypovolaemia should be treated rapidly and aggressively; however, fluid therapy after the initial resuscitation is controversial. Hypotonic fluids should not be administered owing to the risk of hyponatraemia and cerebral oedema. [39] Compared with fluid restriction, fluid therapy aimed at providing maintenance plus correcting the fluid deficit has been reported to result in a more rapid correction of hyponatraemia and deranged ADH. [40], [41] It has also been associated with reduced short-term morbidity and neurological sequelae at follow-up. [42]

Outcome

Bacterial meningitis is associated with significant mortality (5%–10%) and morbidity. In children requiring mechanical ventilation, a mortality rate of 30% has been reported with major neurological sequelae occurring in 33% of survivors.[43]

Encephalitis

Infective Encephalitis

Granerod et al. defined encephalitis as an altered level of consciousness (encephalopathy) lasting more than 24 hours plus two or more of: fever, seizures or focal neurological findings; a CSF pleocytosis of greater than 5 /mm^3 ; abnormal neuroimaging consistent with encephalitis or EEG abnormalities.[44] Of note, infants might exhibit non-specific symptoms including poor feeding, lethargy and fevers as the only detectable symptoms of encephalitis.

Common causes of infective encephalitis include herpesviridae enteroviruses (herpes simples, varicella zoster, cytomegalovirus and Epstein–Barr), and respiratory viruses (adenovirus and influenzae). The most significant causes worldwide are the insect-transmitted arbovirus encephalitides including Australian (Ross River and Murray Valley), Japanese B and St Louis. These can cause profound coma and are associated with a significant incidence of long-term neurological deficit.

Herpes simplex encephalitis is the most important diagnosis to consider and cover empirically. EEG, CT scan and MRI can support diagnosis. MRI is more sensitive than CT scans for detecting signs of encephalitis, particularly during the early stages of the illness. CSF PCR testing aids rapid diagnosis.[45] Acyclovir, if used early, improves outcomes and should be commenced when the diagnosis is suspected.

The enteroviruses are important causes of encephalitis in children. In addition, they cause other acute neurological illnesses, including acute flaccid paralysis due to transverse myelitis and Guillain–Barré syndrome.[46] Pleconaril is a promising new antiviral agent that appears to have clinical benefits in enteroviral infections, including CNS disease.[47] Acyclovir is recommended for varicella zoster encephalitis, foscarnet and ganciclovir for cytomegalovirus and oseltamivir for encephalitis due to influenza. [48] The outcome of viral encephalitis is worse in infancy than in older age groups.

Autoimmune encephalitis

Knowledge and understanding of immune-mediated neurologic disorders are expanding rapidly. Several disorders have been described with clinical and laboratory features of encephalitis associated with the presence of autoantibodies to either intracellular or neuronal surface antigens. [49] Of this group of disorders, anti-N-methyl-d-aspartate receptor encephalitis (anti-NMDAR encephalitis) is the condition that most frequently presents in childhood and adolescence. A Californian study of encephalitis epidemiology found anti-NMDAR encephalitis to be more common than the most frequent type of viral encephalitis (enterovirus). [50]

Approximately 60% of children with anti-NMDAR encephalitis present with sudden onset behavioural change, movement disorders (typically oromotor dyskinesia and hyperkinesia), sleep disturbance or psychiatric symptoms such as psychosis or hallucinations. Catatonia fluctuating with periods of agitation has been described. Seizures or status epilepticus can occur. Autonomic instability (fluctuations in HR, BP, temperature as well as gut perfusion) or central hypoventilation necessitating mechanical ventilation may occur during the acute phase of the illness. [51]

Other autoimmune encephalitis subtypes present similar to adult disorders.

Investigation

Once suspected, diagnostic testing should not delay treatment, as time to management impacts long-term outcomes. [51,52] Diagnosis is confirmed by the detection of serum and/or CSF NMDAR antibodies. CSF analysis may reveal mild pleocytosis, elevated protein and oligoclonal bands; however, CSF may be normal. MRI is utilised to exclude differentials and complications as there are no findings specific to NMDA encephalitis. [52] Even though para-neoplastic presentations associated with ovarian, testicular or mediastinal teratomas, Hodgkin lymphoma and neuroblastoma are much rarer in children compared to adults, screening for tumours is still undertaken with abdominal, pelvic and testicular ultrasound followed by abdominal and thoracic MRI.

Management

If present, tumour removal speeds recovery. First-line immunotherapy consists of high-dose methylprednisolone, intravenous immunoglobulin (IVIG) or plasmapheresis and should be administered regardless of whether a tumour is identified and removed. Patients who do not respond or who relapse should be considered for second-line therapy with rituximab or cyclophosphamide. [52]

Supportive medical therapy is often required; sedation may be needed for movement disorders to avoid complications and agitation might require pharmacological as well as non-pharmacological management. [52]

Outcome

Recovery from anti-NMDAR encephalitis is slow, over weeks to months. Prolonged hospitalisation and the need for rehabilitation are not unusual. Complete recovery is reported in at least 50% of children and adolescents and can be improved with prompt treatment, with another 30% considered to have a good outcome at 2 years. Cognitive sequelae include impaired memory and executive functions. Relapse occurs in 10%–15% of patients. [52]

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is defined as a monophasic inflammatory CNS demyelination. The condition is one of several demyelinating conditions that occur in childhood including transverse myelitis, optic neuritis and multiple sclerosis. The clinical features of ADEM include a variable extent of encephalopathy (which is required to make the diagnosis), ataxia, hemiparesis, cranial nerve palsies, hypotonic, seizures and polyfocal neurological deficits.[53] Respiratory failure can occur from brainstem involvement or a severely impaired conscious state. Case series have reported a requirement for mechanical ventilation in 11%–16% of children.[54], [55]

ADEM is preceded by a triggering event in 70% of cases, most commonly a non-specific upper respiratory tract infection or occasionally a recent vaccination. Although the precise immunopathogenesis of ADEM is unknown, there is a consensus that ADEM is mediated by an autoimmune reaction with antibody formation to myelin.

Investigation

LP should be performed to exclude infectious encephalomyelitis. There may be a modest elevation of the CSF white cell and red cell counts. CSF oligoclonal bands and raised CSF immunoglobulin levels occur more commonly in multiple sclerosis than in ADEM. MRI can show T2 and FLAIR lesions predominantly involving the deep white matter but can be normal initially and even to the time of recovery.[56] Infective, inflammatory metabolic and rheumatologic conditions can mimic the MRI appearances of ADEM. Therefore it is important to have a systematic approach to investigations for potential differential diagnoses. Red flags that suggest an alternative diagnosis are age of onset of less than 1 year; developmental delay; gradual progression; multisystem involvement; or a family history of consanguinity or severe neurologic symptoms. MRI features that suggest an alternative diagnosis include a single supratentorial white matter lesion, symmetrical white matter involvement or lesions restricted to the brainstem or basal ganglia.[57]

Management

High-dose corticosteroids are considered the treatment of choice. Intravenous methylprednisolone 30 mg/kg/day (maximum 1 g/day) for 3–5 days followed by oral prednisolone tapered over 4–6 weeks often results in rapid clinical improvement and improves long-term outcomes. Other treatment options include IVIG (2 g/kg intravenously total over 2–5 days) and plasmapheresis.[57]

Outcome

Most children with ADEM recover completely, although a small percentage of children have significant neurological and neuropsychological sequelae. The most common neurocognitive abnormality identified at long-term follow-up is impaired attention.[58] Rarely is ADEM fatal. Approximately 20% of children initially diagnosed with ADEM experience a recurrence of neurological symptoms and subsequently receive the diagnosis of multiple sclerosis.[58]

Guillain–Barré Syndrome

Clinical Features

Guillain–Barré syndrome (GBS) is characterised by acute areflexic paralysis with raised CSF protein and normal CSF cell counts. It is the most common cause of acute motor paralysis in children. There is strong evidence to support an autoimmune cause with many patients having raised anti-ganglioside antibodies. Many cases are preceded by symptoms of upper respiratory tract infection or diarrhoea. Infectious agents associated with subsequent development of GBS include *Campylobacter jejuni*, cytomegalovirus, Epstein–Barr virus, varicella zoster virus and *Mycoplasma pneumoniae*. An emerging association between GBS and acute arbovirus infection, including Zika virus, is being closely monitored globally.[59], [60] The syndrome includes a number of peripheral nerve disorders that have been classified based on the distribution of weakness, antibody profiles and nerve conduction studies.[61]

Although most patients develop typical ascending, symmetrical areflexic weakness, GBS may present insidiously with apparent lethargy or loss of motor milestones in the young child. There also may be rapid progression and admission criteria to the ICU, which include respiratory failure, bulbar palsy, severe autonomic disturbance or rapidly progressive weakness.

Sensory loss is usually minimal and transient. Pain in the back and legs, possibly neurogenic in origin, is common and may be the presenting feature. [62] This pain may be severe and is often difficult to control. Papilloedema and encephalopathy occasionally occur. The complications of deep-venous thrombosis and thromboembolism are not common problems in young children but they may occur in adolescents.

Investigations

An LP should be performed ideally before treatment with IVIG is commenced. CSF typically shows a WCC $<10 \times 10^{6}$, while CSF protein is usually raised but may be normal during the first week of illness. Nerve conduction studies may be normal if performed early. Neurophysiological criteria have been used to classify GBS subtypes according to either demyelinating or axonal neuropathies, and whether or not both sensory and motor nerves are involved. [63] Antiganglioside antibodies are raised in some but not all patients.

If there is uncertainty about the clinical diagnosis then brain and spinal cord imaging, as well as screening for infection, should be considered. Contrast-enhanced spinal MRI demonstrates contrast enhancement of spinal nerve roots and the cauda equina in most patients with GBS. [64]

Management

Adequate respiratory care is the basis of minimising morbidity and mortality in GBS. Up to one-third of patients require ventilatory support and, ideally, mechanical ventilation should be undertaken electively. Early indications are increased work of breathing, fatigue, poor cough and progressive bulbar palsy. Hypercarbia is a late sign and should be avoided. In children who are old enough to cooperate, forced vital capacity (FVC) should be monitored during the progressive phase of the illness. Mechanical ventilation should be considered if FVC falls below 15–20 mL/kg. Careful frequent clinical assessment is necessary. Once mechanically ventilated, many patients require some degree of hyperventilation to prevent ‘air hunger’. Although nasotracheal intubation is satisfactory initially, a tracheostomy should be performed if recovery is delayed. This will improve comfort and allow speech via the ventilator generating an air leak around the tracheostomy tube. Successful weaning is unlikely unless vital capacity exceeds 12 mL/kg and maximum negative inspiratory force is at least 20 cm H_2O (2 kPa).

Autonomic dysfunction is an important cause of morbidity and mortality in children with GBS. Airway manipulation or induction of anaesthesia, particularly in the presence of hypoxia, may provoke serious cardiac arrhythmias. Fluctuating blood pressure, urinary retention and gut dysfunction also occur.

Plasma exchange and IVIG are effective therapies. The indications for either are rapid progression, respiratory insufficiency or weakness to the point of being unable to walk unassisted. The strongest evidence for these therapies is from adult trials.[65] Large trials adequately powered to separately test the efficacy of plasma exchange and IVIG in children have not been performed; however, a number of small retrospective studies have described local experiences with these immune therapies in children with mixed results.[66,67] As IVIG has significant potential technical advantages over plasma exchange, IVIG is generally the first-line therapy in children. Indications for IVIG are based on the degree of functional impairment and time from onset of symptoms. The indications are not influenced by the clinical or neurophysiological subtype or the results of antibody screening.

Pain is a common feature of GBS and may have a neuropathic basis. Paracetamol or nonsteroidal anti-inflammatory drugs are useful, while drugs to treat neuropathic pain, including gabapentin, carbamazepine and amitriptyline, may also be beneficial.

The problems of long-term ventilation in a conscious patient, compounded by emotional immaturity, speech failure, fear of procedures and family disruption, make the management of a child with GBS and their family particularly challenging. A sensitive team approach is essential.

Prognosis

The prognosis of acute GBS may be better for children than for adults. Full recovery is likely if the time from maximal deficit to the onset of recovery is less than 18 days. However, complete recovery, despite a longer plateau phase, has been reported. Good recovery can occur in patients who have required ventilation and the need for ventilation may not be a poor prognostic factor in children. [68] Those presenting with a subacute course are at risk of relapse and permanent motor deficits.

Metabolic Encephalopathy

Approximately 0.1% of babies have an inborn error of metabolism. Acute encephalopathy is one of the many ways neurometabolic diseases present in childhood. [69] In general, acute presentations occur in the neonatal period and early infancy. Symptoms are often vague and include lethargy, poor feeding and vomiting. Some inborn errors do not present until later in childhood or even in adulthood. Although older children may present with a chronic encephalopathy, they may also present with an acute metabolic emergency, which is usually precipitated by an inter-current illness or catabolic stress.

Approach to Diagnosis

A careful history and examination may elicit clues to a possible metabolic problem. Family history and history of drug exposure are extremely important. The following readily available investigations are useful to allow broad categorisation and to direct further detailed investigations in conjunction with a metabolic consult: blood gas analysis; blood glucose; serum ammonia; serum lactate; plasma amino acids; blood and urine ketones; and urine metabolic screen for amino, orotic and organic acids. While lactic acidosis and hypoglycaemia can occur in a number of disease states including sepsis, persisting abnormalities require further investigation. Lactic acidosis can be further assessed with measurement of lactate/pyruvate ratio. Figure 96.4 provides an algorithm proposed by Ellaway and colleagues to direct the investigation of metabolic disease presenting in the newborn period based on the metabolic abnormalities detected from baseline investigations. [70] This is best done in collaboration with a metabolic disease specialist or a clinical biochemist.

Management

Initial management includes elimination of toxic metabolites and the administration of calories to switch off catabolism. Metabolic derangements, such as acidosis and hypoglycaemia, should be corrected. The role of ICP monitoring for acute intracranial hypertension is controversial; however, patients with suspected raised ICP, and unconscious patients, should receive standard modalities of support including intubation and mechanical ventilation. Hyperammonaemia should be managed by stopping enteral feeds to limit protein intake. Agents, such as arginine and sodium benzoate, can be administered to increase ammonia metabolism. Providing calories intravenously in the form of glucose and fat limits the extent of catabolism and thereby helps to curtail the metabolic crisis. Haemodiafiltration is effective at controlling hyperammonaemia (urea cycle defects), leucine toxicity (maple syrup urine disease) and propionic acid (propionic acidaemia).[71, 72]

Hypoxic–Ischaemic Encephalopathy

The most common causes of hypoxic–ischaemic encephalopathy outside the neonatal period are:

- near-miss sudden infant death syndrome
- immersion
- accidents, including drug ingestion and strangulation
- inflicted injury

Pathology

The brain requires a continuous supply of oxygen and glucose to maintain energy production and interruption of either can lead to energetic failure and neuronal injury. Following a hypoxic–ischaemic insult, the brain is vulnerable to further damage in the reperfusion phase, especially from reactive oxygen species.

Management Post-Cardiac arrest

Cardiac arrest in children, unlike in adults, is often secondary to respiratory causes with secondary cardiac arrest and cause significant mortality and morbidity. Improvements in quality of acute resuscitation have led to a survival benefit, unfortunately, this has not yet improved neurological outcomes. In cases of out-of-hospital cardiac arrest, full resuscitation must be attempted while the history is sought.

Irrespective of the aetiology of the cardiac arrest, ischaemia and reperfusion that occur during and after the resuscitation phase can result in damage to multiple organ systems and can lead to post-cardiac arrest syndrome. [73]

One of the critical determinants of neurological outcome is the initiation of post-cardiac arrest care as soon as return of spontaneous circulation (ROSC) is achieved. [73–75] This should be integrated as a standard of care in treating cardiac arrest patients who attain ROSC. Like any other form of acute brain injury, the goal of post-cardiac arrest care is to limit ongoing injury and provide organ support, especially in the initial 72 hours post-cardiac arrest.

Comatose patients with a GCS score <9 are best managed by mechanical ventilation and sedation for at least 48–72 hours. Ventilation should be targeted at normocapnoea, and hyperventilation avoided owing to the risk of further cerebral ischaemia. [74], [75] Haemodynamic disturbance may develop because of primary cardiac dysfunction or hypovolaemia secondary to fluid loss from capillary leak syndrome. Circulating volume should be restored, and vasoactive agents considered, to improve the state of the circulation. Patient’s post-cardiac arrest is at high risk of clinical and sub-clinical seizures, and if possible, they should be monitored by continuous EEG (cEEG) monitoring and treated accordingly.

Targeted temperature management (TTM) is important in all patients with acute brain injury and it is particularly important as a part of post-cardiac arrest care. It is important to highlight that in the absence of active TTM, most post-arrest patients will develop fever early after resuscitation. Therefore regardless of whether 37°C or lower target temperature is selected; TTM requires active temperature management and shivering prevention. In post-cardiac arrest patients, TTM induction should be achieved as soon as possible after ROSC and maintained for 72–96 hours at least. Avoidance of temperature fluctuations in the maintenance phase is crucial. The cooling technique most commonly used in the paediatric population is external surface cooling, although internal cooling is possible. [9-13]

Hyperglycaemia has been associated with a worse prognosis and, although it may simply be a marker of injury severity, active treatment has been advocated. The role of invasive ICP measurement is limited as intracranial hypertension usually occurs only in the setting of severe injury and poor outcomes. [76]

Prognosis

Prognostication in post-cardiac arrest patients remains challenging. Factors that should be considered include the duration of cardiopulmonary resuscitation (CPR), the cause of arrest, pre-existing medical conditions, the location of the arrest, whether the arrest was witnessed and, the duration of arrest before resuscitation commenced. [77] In immersion injuries in young children, full recovery may be possible despite prolonged ischaemia if sufficient rapid cerebral cooling has occurred. In these cases, the onset of ischaemia may be delayed by bradycardia with preferential cerebral flow (the ‘diving reflex’).

Ultimately, use of a multimodal approach (i.e., combining clinical exam, electrophysiology and neuroimaging) for prognostication has been widely recommended.

Clinical evaluation

Bilateral absence of pupillary responses is the most specific indicator of poor prognosis but depends on the timing of assessment. At 72 hours following ROSC, bilateral absence of a pupillary light reflex is highly specific for poor outcome (false positive rate of 0%); however, the sensitivity is low (18%–24%). [77] An absent corneal reflex is also usually associated with a poor outcome but is slightly less specific than the pupillary reflex.

Another clinical sign associated with poor prognosis is status myoclonus. In post-cardiac arrest patients, status myoclonus starting within 48 hours from ROSC is consistently associated with poor outcomes. [77]

Electrophysiological studies

Somatosensory evoked potentials (SSEPs) are the most useful aid to prognostication. Bilateral absence of cortical SSEPs is predictive of a poor outcome provided that the test is technically well-performed. One report of 109 children with severe brain injury concluded that, with appropriate patient selection, the positive predictive value for poor outcome of bilaterally absent SSEPs is 100% (95% confidence interval 92%–100%). [78]

EEG background patterns along with the presence or absence of EEG reactivity can be used in addition to clinical criteria to support prognostic decision-making. EEG background patterns associated with increased odds of death and unfavourable neurologic outcomes are a slow-disorganised pattern, a discontinuous or burst suppression pattern and an attenuated or flat pattern.

Neuroimaging

CT scan of the brain, although helpful in ruling out a cerebral cause of cardiac arrest, has limited value in neuro-prognostication of comatose cardiac arrest survivors. While the presence of abnormal CT findings, including loss of grey-white matter differentiation and cistern effacement, early after resuscitation from out-of-hospital paediatric cardiac arrest are highly specific for mortality and unfavourable neurologic outcome, a normal CT scan early after resuscitation has little prognostic significance. MRI, best performed 3–5 days post ROSC, provides a more sensitive indication of brain injury after cardiac arrest. The use of diffusion-weighted imaging and apparent diffusion coefficient values can quantify the degree of injury.

Acute ischaemic stroke

Recognition of acute ischaemic stroke in children is significantly limited by a lack of awareness among health-care workers as well as the public that infants and children can suffer a stroke and that brain-saving reperfusion therapies are available for infants and children. National paediatric stroke guidelines are needed to supplement international guidance [79] and local adaptation as code stroke processes are available for some regions. [80]

Haemorrhagic stroke

Arteriovenous malformations (AVM) are a more common cause of haemorrhagic stroke in children than aneurysms (Box 96.2). [81] The presenting features are similar to those seen in adults and include sudden severe headache, altered conscious state and seizures. Diagnosis can usually be made by a brain CT scan with contrast (with angiography from the aortic arch upwards). Raised ICP, if present, requires a time-critical neurosurgical intervention to either manage hydrocephalus with an extra-ventricular drain (EVD) or decompress the mass lesion. Following initial diagnosis, further investigations are required to elucidate the underlying cause. Delayed neuroimaging and digital subtraction angiography can define the neurovascular lesion if present. Bloods to exclude haematological disorders include coagulation profile and platelet count. Definitive treatment requires a multidisciplinary team approach as surgical or endovascular treatment options of neurovascular lesions need to be planned carefully. A period of close observation is required as children may be at greater risk of rebleeding from an AVM than adults. The efficacy of therapies (e.g. calcium channel blockers) used to prevent vasospasm in adults following aneurysmal sub-arachnoid haemorrhage has not been studied in children but is still recommended given the high risk of additional morbidity. Sequelae of haemorrhagic stroke include hemiparesis, aphasia, seizures and hydrocephalus and children require close follow-up typically by the interdisciplinary rehabilitation service.

Spinal Injury

Incidence

Paediatric spinal trauma is relatively rare, comprising <5% of all spinal injuries. Approximately 5% of children with severe head trauma will have a cervical spine injury. [82] The most common causes of paediatric spinal trauma are motor vehicle collision, as either a pedestrian or passenger, falls and diving injuries. Sports-related injuries are uncommon.

Pathophysiology

The patterns of spinal injury in children differ from those seen in adults in many ways. Spinal cord injury without radiographic abnormality (SCIWORA) occurs almost exclusively in children (20%–60% of spinal cord injuries if not imagined with MRI). It is associated with a high incidence of complete neurological deficits. Spinal injury in the first decade of life occurs most commonly in the first two cervical segments, with atlanto-axial rotatory subluxation, bony or ligamentous injuries or SCIWORA and severe cord injury. Although not as common as upper cervical injuries, lower cervical injuries (below C4) do occur in young children, [82] while injury may occur at more than one level. Atlanto-axial rotatory subluxation may occur after minor trauma or without an identifiable precipitating event and is rarely associated with neurological deficits. However, ligamentous injury is more likely to be associated with permanent neurological deficit than high cervical fractures. As the bony spine matures, the pattern of injury becomes more adult-like, with lower cervical and thoracic injuries seen in the second decade. [82]

Clinical Features

The immediate effects of spinal cord damage are similar at any age. Frequently, an associated head injury can render clinical assessment extremely difficult; confirmation of cord injury is sometimes delayed. Clues to the diagnosis in the unconscious patient include:

- flaccidity, immobility and areflexia below the level of the lesion
- hypoventilation with paradoxical chest movement; this occurs in the absence of airway obstruction where the intercostal muscles are paralysed and the phrenic nerves are intact
- apnoea with rhythmic flaring of the alae nasi (Duncan's sign), which is seen when the lesion is above C3
- hypotension with inappropriate bradycardia and cutaneous vasodilatation below the level of injury, due to absent spinal sympathetic outflow
- priapism.

There may be visible or palpable evidence of trauma to the spine and surrounding soft tissues, including retropharyngeal or retrolaryngeal haematomas. Spinal shock is common with temporary complete loss of function. As this resolves, after 3–5 days, reflexes progressively return, usually starting with bulbocavernosus and anal reflexes. Incomplete lesions, including the Brown–Sequard cord hemisection, and anterior and central cord syndromes may become apparent at this stage.

Investigations

Resuscitation, including emergency intubation, should not be delayed to perform neuroimaging, typically a trauma CT scan in the first instance. MRI is useful both in the acute setting and in assessment at later stages and is now accepted as the standard for identifying haemorrhage, contusion or compression of the cord and can inform time-critical neurosurgical intervention. SCIWORA was defined in an era before MRI was routinely available. If intramedullary lesions are demonstrated with MRI, permanent neurological deficits are more likely.[83], [84] SSEPs may be useful to evaluate the integrity of the spinal cord, particularly in the comatose patient.

Management

Achieving control of airway, ventilation and circulation is always the first priority. If tracheal intubation is indicated, and if stability of the neck is unknown, skilled assistance is necessary to immobilise the head and neck and to prevent flexion or extension. Because of the sympathectomised state in high cord injuries, relatively low blood pressure can remain problematic even after hypovolaemia is corrected. Significant hypotension becomes more likely the higher the lesion and the younger the patient. Haemodynamic support with a vasoconstrictor, such as norepinephrine (noradrenaline), is useful if hypotension is problematic following restoration of intravascular volume. As up to 20% of patients will have multiple traumas, many will require major surgical procedures, during which the spinal cord must remain protected. If muscle relaxants are required 2–3 days following the injury, suxamethonium is contraindicated owing to the risk of fatal hyperkalaemia.

Trials of high-dose steroids in adults with acute spinal injury have been controversial [85], [86]; however, there are no studies specific to children and steroid administration is not recommended in children.[87]

As with brain injuries, preventing secondary injury is vital. Adequate perfusion of the spinal cord should be ensured, as autoregulation of blood flow is lost after trauma.

The incidence of venous thromboembolism after spinal injury in adolescents approaches that in adults; therefore patients in this age group should receive standard prophylaxis. Venous thromboembolism is rare in prepubertal children (approximately 1%), and the risk–benefit ratio of routine prophylaxis in this age group is unknown.[88] There should be early consultation with a specialised spinal injuries unit. Optimal rehabilitation requires a team of orthopaedic and neurosurgeons, rehabilitation specialists, nurses, physiotherapists, occupational therapists, psychiatrists, social workers and schoolteachers.

Prognosis

Recovery after spinal injuries in children may be better than in adults. Similar prognostic criteria still apply especially for more severe injuries and include MRI and the American Spinal Injury Association Impairment Scale (ASIA Score).

Paediatric trauma

Kevin McCaffery

Introduction

In developed countries, trauma continues to be the leading cause of death in children over 1 year of age. Even in severely injured children, however, mortality is low (~5%), [1] making it likely that even intensive care physicians practicing in adult units may be asked at some point in their career to assist in the stabilisation of a child presenting with trauma prior to retrieval to a paediatric facility.

While many of the principles of trauma management are common to both paediatric and adult patients, key differences exist. This chapter aims to assist primarily adult-focused intensivists in the provision of immediate care to injured children while emphasising relevant anatomical, physiological or pathological differences.
